Abstract

Acute myeloid leukemia (AML) is a heterogeneous hematologic malignancy characterized by subpopulations of leukemia-initiating or leukemia stem cells (LSC) that give rise to clonally related non-stem leukemic blasts. The LSC model proposes that since LSC and their blast progeny are clonally related, their functional properties must be due to epigenetic differences. In addition, the cell of origin of LSC among normal hematopoietic stem and progenitor cells (HSPCs) has yet to be clearly demonstrated. In order to investigate the role of epigenetics in LSC function and hematopoietic development, we profiled DNA methylation and gene expression of CD34⁺CD38⁻, CD34⁺CD38⁺ and CD34⁻ cells from 15 AML patients, along with 6 well-defined HSPC populations from 5 normal bone marrows using Illumina Infinium HumanMethylation450 BeadChip and Affymetrix Human Genome U133 Plus 2.0 Array. To define LSC and blast functionally, we performed engraftment assays on the three subpopulations from 15 AML patients and defined 20 LSCs and 24 blast samples. We identified the key functional LSC epigenetic signature able to distinguish LSC from blasts that consisted of 84 differential methylations regions (DMRs) in 70 genes that correlated with differential gene expression. *HOXA* cluster genes were enriched within the LSC epigenetic signature. We found that most of these DMRs involve epigenetic alteration independent of underlying mutations, although several are downstream targets of genetic mutation in epigenome modifying enzymes and upstream regulators. The LSC epigenetic signature could predict overall survival for AML patients independent of known risk factors such as age and cytogenetics. We characterized epigenetic changes during normal human hematopoietic development and identified key novel regulators for

hematopoietic differentiation such as *HMHB1* and *MIR539*. We found that global hypomethylation is a critical mechanism of lineage commitment in human hematopoiesis. Our DNA methylation analysis in human hematopoiesis revealed variable epigenetic regulation compared to murine hematopoiesis. Furthermore, we found that LSC populations formed two distinct clusters resembling either lymphoid-primed multipotent progenitors (L-MPPs) or granulocyte/macrophage progenitors (GMPs). These results provide the first evidence for epigenetic variation between LSC and their blast progeny in AML, and its prognostic power. We also provided comprehensive methylome map of human hematopoiesis and identified epigenetically distinct subgroups of AML LSCs that likely reflect the cell of origin.

Andrew P. Feinberg, M.D., M.P.H.

Acknowledgments

Over the past 6 years of my graduate study, many people have contributed to my personal and professional growth. It would be impossible to mention everyone who helped me to finish this long journey in graduate school, but I wish to acknowledge couple people here.

Foremost, I would like to express my deepest gratitude to my thesis advisor, Dr. Andrew Feinberg for his relentless support, patience, and motivation. Andy has given insightful suggestions and comments on any subject that we had a conversation on. He also taught me how I should behave in academic setting as a professional scientist. Without Andy's guidance and persistent help throughout my graduate study, this thesis would not have been possible.

I would like to thank to Dr. Ravindra Majeti at Stanford who has been a wonderful thesis committee member, the second reader of my thesis, and collaborator. Ravi has provided his expert advices and valuable knowledge in leukemia and hematopoiesis throughout this thesis. His comments and suggestions were an enormous help for me to learn knowledge in a different field.

I am deeply grateful to my thesis committee chair, Dr. Roger Reeves for his generous support and encouragement for this thesis and my career, and thesis committee member, Dr. Donald Small for his advices and support.

I wish to acknowledge Dr. Yunje Cho, my undergraduate thesis advisor, for his encouragements and advices, which have been motivation for my PhD work.

I am deeply grateful to my collaborators, Dr. Andrew Gentles and Dr. Rafael Irizarry for their statistical advices and comments, and Dr. Bo Dai for the essential part of functional experiments of this thesis. I would like to express my gratitude toward the AML patients and their family members for their decisions to provide valuable samples for this thesis.

I could not have done my PhD work without the advices and supports provided by current and former Feinberg lab members who have had impact on every aspect of this thesis. Akiko Doi and Brian Herb have always offered great feedbacks for experiments and encouragements to move forward during my graduate course work. It has been very lucky to have Amy Vandiver as my bench mate for past 5 years, who has provided useful suggestions for science, and warm support for any decision related to graduate course work and even personal life. I'm grateful to Carolina Montano, Lindsay Rizzardi, Hwajin Lee, Xin Li, Yun Liu, Hong Ji, Peter Murakami, Michael Multhaup, Varenka Rodriguez, and Elisabet Pujadas for useful discussions, feedbacks, and their friendship. I thank to Rakel Tryggvadottir and Arni Runarsson for their experimental help.

I am grateful to Samsung Scholarship that has offered financial support for first five years, and Mogam Science Scholarship Foundation for financial support for last year of my graduate study.

Many friends have supported and helped me to stay centered throughout past 6 years. I have been fortunate to have warmhearted CMM classmates, who have helped me to adapt to a new culture. Friends of Korean community and in Korea have been always there to listen to my problems, and given me great emotional support.

Last but not least, this long journey in graduate school would have been impossible without the warm support of my family. My grandparents, Jongsung Jung and Oksoon Cho have offered priceless life lessons and taught me how to be a polite person. My parents, Insoo Cheong and Geumsook Choi, have provided unconditional love and support for any decision that I have made. My two younger sisters, Gayoung Jung and Chaeyoung Jung have been the best friends throughout my life giving me emotional support.

I will always be grateful to all the individuals mentioned above who shaped me as a professional scientist.

Chapter1

Introduction

1. Epigenetics

Overview

Epigenetics is the study of information that is heritable after cell division other than the primary DNA sequence. Epigenetics is involved in many cellular processes such as embryonic development, differentiation, and an interaction with environmental stimuli. Mechanisms of epigenetics include DNA methylation, histone modification, chromatin factors, chromatin structure, and noncoding RNAs. Dysregulation of the epigenetic modifications is known to be involved in many diseases such as cancer.

Definition (historical and modern)

Conrad Waddington first coined the term ‘epigenetics’ in 1942 as a mechanism of how genotype brought about phenotype during development (Waddington, 2012). He proposed the ‘Epigenetic landscape’ as a model for cellular development that a ball is rolling down a hill to the lowest points (Goldberg et al., 2007). The ‘Epigenetic landscape’ is a metaphor of how a cell (a ball) decides its fate (the lowest points) (Goldberg et al., 2007). The role of epigenetics is evident in multicellular organisms, where the vast majority of cells have the same genomic sequence, yet exhibit distinct cellular phenotypes. All cells in the human body originate from the same source, pluripotent stem cells in the inner cell mass (ICM) of a blastocyst. The pluripotent stem cell differentiates into different types of cells such as neurons, hepatocytes, or tubular epithelial cells, which constitute brain, liver, and kidney, respectively. As all these cells come from the pluripotent stem cells in the ICM, they have the same genomic sequence,

yet display distinct phenotypes and functionality (Figure 1.1). In order to investigate the role of epigenetics in different levels of biological processes systematically, NIH Roadmap Epigenomics Project was launched in 2008 (Bernstein et al., 2010). The NIH Roadmap Epigenomics Project defines epigenetics as both heritable and other stable and long-term changes in gene expression regulation of a cell. Collective efforts to provide a public resource of epigenomic information have generated comprehensive epigenomic maps of DNA methylation, histone modifications, DNA binding protein, chromatin accessibility, and noncoding RNAs in diverse cell types and tissues (Bernstein et al., 2010; Roadmap Epigenomics et al., 2015). Among the epigenetic modifications, DNA methylation will be the focus of this thesis.

DNA methylation

In mammals, DNA methylation is generally referred to as a covalent modification in which a methyl group is attached to the fifth position of cytosine in CpG dinucleotides. Note that non-CG methylation in CHG and CHH (H=A, C or T) contexts has been reported in stem cell, neuron, and other differentiated tissues, yet its functional role is still an active research area (Lister et al., 2013; Lister et al., 2009; Ramsahoye et al., 2000; Schultz et al., 2015). DNA methylation is established and maintained by three DNA methyltransferases: DNMT1, DNMT3A and DNMT3B (Li et al., 1992; Okano et al., 1999). These enzymes use S-adenosyl methionine (SAM) as a methyl group donor. DNMT1 is responsible for methylation of hemimethylated DNA after DNA replication, while DNMT3A and DNMT3B are able to methylate both hemi and unmethylated DNA,

so serve as *de novo* methyl transferases (Leonhardt et al., 1992; Okano et al., 1999). The human genome contains about 28 million CpGs and 60-80% of those are generally methylated (Smith and Meissner, 2013). A small portion (~10%) of CpGs, not methylated clusters together, and thus establishes a genomic region called *CpG islands*, which are predominantly located in the promoter of coding genes (Bird, 1986; Deaton and Bird, 2011). Maintaining the unmethylated status of CpG islands requires transcription factor binding, deposition of histone variant H2A.Z, and trimethylation of histone H3 at lysine4 (H3K4me3) that inhibit the binding of DNA methyltransferases (Brandeis et al., 1994; Conerly et al., 2010; Macleod et al., 1994; Otani et al., 2009). The repression of CpG island-promoters genes is largely mediated by histone modification, particularly trimethylation of histone H3 at lysine27 (H3K27me3), and polycomb proteins (Bartke et al., 2010; Brinkman et al., 2012; Jones, 2012). However, DNA methylation at CpG island promoters does occur to suppress CpG island containing genes that are targets of specific biological processes such as X-chromosome inactivation and genomic imprinting (Jones, 2012).

Recently, the CpG-island centric view has been challenged, as methods to measure DNA methylation have been improved with the development of array and sequencing technology. There has been an accumulation of evidence that other genomic regions also have important roles in development and disease progression. A large portion (~80%) of methylation differences among different tissues in human and mouse has been reported to not occur in CpG islands, but ‘CpG island shores’, located up to 2kb distant from CpG islands (Irizarry et al., 2009). Besides the differential methylation involved in normal tissue development, most differentially methylated regions (DMRs)

that distinguish human colon cancer from normal colon tissues, human induced pluripotent stem (iPS) cells from fibroblast, and murine hematopoietic stem and progenitor cells (HSPCs) are located in CpG island shores (Doi et al., 2009; Hansen et al., 2011; Irizarry et al., 2009; Ji et al., 2010). Interestingly, the tissue-specific, cancer-specific and reprogramming-specific DMRs (tDMR, cDMR, and rDMR, respectively) showed statistically significant overlap with each other, indicating that there may be a core set of genomic regions targeted for epigenetic regulation during normal development and disease progression. In addition, DNA methylation at CpG island shores showed strong inverse correlation with gene expression, while DNA methylation at CpG islands did not show a statistically significant correlation with gene expression in these data sets, suggesting functional importance of CpG island shores in diverse biological contexts (Doi et al., 2009; Irizarry et al., 2009; Ji et al., 2010).

In cancer epigenetics, it has long been known that hypermethylation in CpG islands is a core mechanism of cancer progression, yet various types of alterations have been observed in other genomic regions. For example, in colon cancer, hypermethylation is a major type of change in CpG island shores (Irizarry et al., 2009). A large-scale change in half the genomic regions called hypomethylated ‘block’ has been identified in solid tumors with increased variation in expression of genes inside the blocks (Hansen et al., 2011; Timp et al., 2014; Timp and Feinberg, 2013). Stochastic variation of DNA methylation in cDMRs distinguished solid tumors from its normal counter parts, and different stages of tumors (Hansen et al., 2011; Timp et al., 2014). Thus, epigenetic dysregulation of increased epigenetic plasticity with genetic mutation would be a critical mechanism of cancer progression (Feinberg et al., 2006; Timp and Feinberg, 2013).

Recently, this hypomethylated large domain has also been observed in ageing phenotype. Sun-exposed epidermal samples in older people (Age>65) showed the hypomethylated blocks that overlapped with blocks in colon cancer and squamous cell carcinoma (Vandiver et al., 2015). The hypomethylated blocks largely overlap with higher order genomic regions such as large organized chromatin lysine-modifications (LOCKS) or nuclear lamin-associated domains (LADs), suggesting the altered large scale DNA methylation is associated with dysregulation of the large scale genomic regions in disease progression.

Besides CpG islands and shores, gene body methylation has received a lot of attention, yet its functional importance remains to be determined. DNA methylation in gene bodies has traditionally been thought to silence repetitive DNA sequences, such as retroviruses and LINE elements (Yoder et al., 1997). Recent evidence suggests that gene body methylation positively correlates with gene expression in normal tissues and cancer samples (Kulis et al., 2012; Varley et al., 2013; Yang et al., 2014). Potential mechanisms of gene body methylation in the regulation of gene expression include effects on transcription elongation or splicing regulation (Jones, 2012; Laurent et al., 2010). However, the functional role of gene body methylation in transcription regulation is not evident yet, compared to other genomic regions.

DNA demethylation

DNA methylation is a stable covalent modification on genomic sequences, while it is also reversible. Both passive and active loss of DNA methylation can occur through

diverse biological processes. Passive DNA demethylation occurs during consecutive DNA replication in the absence of functional DNMT1 activity (Kohli and Zhang, 2013). Recent advances in identification of enzymes involved in methyl group removal from cytosine have facilitated our understanding of active DNA demethylation process. Ten-eleven translocation (TET) family enzymes, TET1, TET2, and TET3 are able to oxidize methyl cytosine and generate intermediate products including 5-hydroxymethylcytosine (5hmC), 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC) (Ito et al., 2010; Ito et al., 2011; Kriaucionis and Heintz, 2009; Tahiliani et al., 2009). These oxidized 5mC intermediates undergo further removal processes: passive removal by sequential DNA replication, direct removal, or DNA repair pathway-associated removal (Kohli and Zhang, 2013). Among these, the base excision repair (BER) pathway has been actively investigated. Thymine DNA glycosylase (TDG), an enzyme involved in BER is known to have an ability to remove thymine from G-T mismatches from normal DNA context (Cortazar et al., 2007). Recently, it has been reported that TDG is required for epigenetic stability in embryonic development in mice (Cortellino et al., 2011). Since TDG has an ability to remove thymine from G-T mispair, it has been hypothesized that 5mC or oxidized 5mCs may be converted to thymine or uracil by deaminase first. Several studies have suggested that AID/APOBEC enzymes, known cytosine deaminases, play a role in deamination of the 5mC in reprogramming or embryonic development (Bhutani et al., 2010; Kumar et al., 2013; Popp et al., 2010). Yet, a controversy over the role of the deaminases in DNA demethylation still exists, due to their limited enzyme activities on modified cytosines (Kohli and Zhang, 2013). In addition to the deaminase-mediated BER, other studies have shown that TDG can directly remove 5fC and 5caC (He et al., 2011;

Maiti and Drohat, 2011). DNA demethylation is implicated in multiple biological processes including pre-implantation methylation dynamics, primordial germ cell (PGS) reprogramming, maintenance of stem cell pluripotency and cancer development (Kohli and Zhang, 2013).

Methods to measure DNA methylation

Array-based (CHARM and Illumina Infinium HumanMethylation450 BeadChip)

In 2008, the comprehensive high-throughput arrays for relative methylation (CHARM) method was developed to provide the first platform to interrogate DNA methylation in a genome-wide and non-CpG island biased manner (Irizarry et al., 2008). CHARM utilizes a methylation dependent restriction enzyme, McrBC, that cleaves DNA containing methylated cytosines. Sheared genomic DNA is divided into two fractions; one for undigested control and the other for McrBC digestion. The undigested control and McrBC digested samples undergo size selection. The size selected DNA is amplified and hybridized to a tiling array that excluded isolated CpGs. The log-ratio of the signal intensities from the array of the untreated and McrBC treated samples (M-value) is measured. Since methylation status of neighboring CpGs is likely to correlate with each other, the measured M-value is averaged within a given genomic region of interest. This process is called ‘Genome-weighted smoothing’ that improves the accuracy and specificity of measuring methylation at CpG sites (Irizarry et al., 2008). Many studies have applied CHARM to identify genome-wide differential methylation in different model systems: tissue development, cellular reprogramming, hematopoiesis, cancer, and

behavior of social insects (Doi et al., 2009; Herb et al., 2012; Irizarry et al., 2009; Ji et al., 2010; Kim et al., 2010; Kim et al., 2011).

Illumina has endeavored to develop commercially available arrays to measure genome-wide DNA methylation, and produced Infinium HumanMethylation27 BeadChip (27K) and 450 BeadChip (450K). As implied in its name, 27K covers about 27000 CpG sites, mostly enriched in CpG islands, while 450K covers about 480000 CpG sites encompassing diverse genomic regions selected from previous studies for tDMR, cDMR, rDMR, non-CpG methylated sites, and miRNA promoter regions other than CpG islands. In this section, we will focus on 450K, the method used in this thesis. The 450K array utilizes bisulfite conversion and genotyping of the C/T polymorphism method to detect methylation at a CpG site quantitatively. Methylated cytosine remains as cytosine, but unmethylated cytosine is converted to uracil after bisulfite conversion (Clark et al., 1994; Frommer et al., 1992). Note that this method does not distinguish 5mC from 5hmC, because 5hmC remains as cytosine after bisulfite conversion (Huang et al., 2010). For the 450K array, DNA sample is treated with bisulfite, then amplified by PCR. The bisulfite treated and amplified DNA is hybridized on the 450K array that returns the measurement of methylation level at CpG sites on a probe on the array (Dedeurwaerder et al., 2011).

Sequencing-based (Bisulfite pyrosequencing and whole-genome bisulfite sequencing (WGBS))

Two different levels of sequencing technology are widely used to measure DNA methylation: bisulfite pyrosequencing for a small genomic regions and WGBS for

genome-wide level. Bisulfite pyrosequencing is based on bisulfite conversion. As explained above, methylated cytosine is not affected by bisulfite treatment, while unmethylated cytosine is converted to uracil, and eventually thymidine after PCR amplification. Step-wise incorporation of deoxynucleotide triphosphates (dNTPs) during sequence extension releases pyrophosphates, which are converted to ATP by sulphurylase. Then, luciferase converts luciferin to oxyluciferin using ATP and produces light, which will be detected by pyrosequencing machine. The intensity of the released light is proportional to the amount of the nucleotides incorporated at a single base site. The C to T ratio can be quantitatively measured by the amount of dCTP or dTTP incorporation at a cytosine of a CpG site which can be inferred from the intensity of light released (Bassil et al., 2013). Bisulfite pyrosequencing has been used to detect quantitative methylation and individual CpG sites or to validate results from array-based methods (Doi et al., 2009; Herb et al., 2012; Ji et al., 2010; Kim et al., 2010).

Next-generation sequencing technology has allowed the development of WGBS, enabling researchers to investigate quantitative DNA methylation level at CpG sites genome-wide. WGBS uses bisulfite conversion as in bisulfite pyrosequencing, but the bisulfite converted DNA undergoes next-generation sequencing instead of region specific amplification. The high throughput sequencing data returns read numbers of cytosine versus thymidine, therefore yielding a quantitative measure of DNA methylation at all CpG sites in the genome (Laird, 2010; Lister et al., 2009). Several statistical methods and software packages have been developed to analyze the WGBS data: BSmooth, Bismark, and so on. Among these packages, BSmooth offers relatively accurate measurement of DNA methylation at individual CpG sites from low coverage WGBS data by using

smoothing algorithm (Hansen et al., 2012). WGBS enables researchers to discover not only DMRs, but also non-CG methylation in stem cells and large genomic DNA methylation changes in cancer and sun exposed skin in elderly people (Hansen et al., 2011; Lister et al., 2009; Vandiver et al., 2015).

2. Hematopoiesis

Overview

Hematopoiesis is one of the best studied, but complicated developmental systems. It consists of a hierarchical process initiated by hematopoietic stem cells (HSCs) that differentiate into other hematopoietic progenitor cells and eventually produce all the mature differentiated blood lineages (Chao et al., 2008; Doulatov et al., 2012). Experimental investigation of the hematopoietic system in the mouse was pioneered by Till and McCulloch who identified a small subset of cells from the mouse bone marrow which could self-renew and form myeloerythroid colonies (Becker et al., 1963; Till and Mc, 1961). These studies facilitated other investigators to develop assays such as the in vitro clonal assay combined with fluorescence-activated cell sorting (FACS), to identify and characterize hematopoietic stem and progenitor populations in mouse and human (Chao et al., 2008; Doulatov et al., 2012). The classical model of hematopoiesis demonstrates that fully differentiated blood cells constitute two major lineages: myeloid and lymphoid. Myeloid lineage cells include granulocytes, monocytes, erythrocytes, and megakaryocytes that give rise to platelets. Lymphoid lineage cells include T, B, and natural killer (NK) cells, involved in immune responses (Doulatov et al., 2012).

Human hematopoiesis

Identification of stem and progenitor cells (HSPCs) has promoted our understanding of human hematopoiesis. Multiple different cell surface markers were identified and used for isolation of HSPCs. For example, CD34 is a well known marker for the HSPCs that possess regenerative potential (Civin et al., 1984; DiGiusto et al., 1994; Krause et al., 1996). Among these CD34⁺ HSPCs, additional markers such as CD90, CD38, CD45RA, CD123, and CD10 enable researchers to isolate different components of the hierarchy. Several studies have demonstrated that HSC resides in Lin-CD34⁺CD38⁻CD90⁺ population (Chao et al., 2008). Further investigation to identify downstream progenitors of HSC has established that multipotent progenitor (MPP) cells are contained in Lin-CD34⁺CD38⁻CD90⁻CD45RA⁻ (Majeti et al., 2007). After HSC gives rise to MPPs, MPPs further differentiate into progenitors for myeloid or lymphoid lineages. In myeloid lineage differentiation, the common myeloid progenitors (CMPs) develop into either GMPs or megakaryocyte/erythrocyte progenitors (MEPs). Interleukin-3 receptor alpha chain (CD123) and CD45RA distinguish CMP, GMP and MEP: CMPs reside in Lin-CD34⁺CD38⁺CD123⁺CD45RA⁻, GMPs in Lin-CD34⁺CD38⁺CD123⁺CD45RA⁺, and MEPs in Lin-CD34⁺CD38⁺CD123⁻CD45RA⁻ (Chao et al., 2008). Lymphoid lineage differentiation is more complicated, since L-MPP is able to generate lymphoid lineage cells, as well as monocytes, macrophages and dendritic cells by differentiating into GMP. This L-MPP population is contained in Lin-CD34⁺CD38⁻CD90⁻CD45RA⁺ (Doulatov et al., 2010; Goardon et al., 2011). This thesis will demonstrate DNA methylation

differences among human HSPCs and compare epigenetic plasticity between human and mouse hematopoietic development.

DNA methylation in normal hematopoiesis

Two studies have investigated genome-wide DNA methylation in mouse hematopoietic development using array or sequencing based methods (Bock et al., 2012; Ji et al., 2010). Ji et al. performed CHARM examining 4.6 million CpG sites throughout the genome for MPPs, common lymphoid progenitors (CLPs), CMPs, GMPs, and thymocyte progenitors (DN1, DN2, DN3). Global methylation changes were involved in fate decision at the myeloid or lymphoid commitment stage: decreased methylation for myeloid and gain of methylation for lymphoid commitment. This first comprehensive methylome map of hematopoietic progenitor cells in murine hematopoiesis identified potential novel regulators such as *Arl4c* and *Jdp2*, as well as previously known transcription factor for hematopoietic differentiation, *Meis1*. This study demonstrated DNA methylation is a core mechanism for hematopoietic development, and epigenetic plasticity regulates lineage commitment (Ji et al., 2010). In another study, Bock et al. investigated genome-wide DNA methylation of HSCs, MPP1s, MPP2s, CMPs, CLPs, GMPs, MEPs, CD4-T cells, CD8-T cells, B cells, erythrocytes, granulocytes, monocytes using reduced representation bisulfite sequencing (RRBS). They observed similar pattern of epigenetic plasticity in cell fate decision: hypermethylation in CLPs and hypomethylation in CMPs. DNA methylation has played a crucial role for silencing of genes involved in myeloid differentiation in lymphoid lineage cells and vice versa. For

example, promoters of key transcription factor (TF) for myeloid differentiation such as *Tal1*, or binding sites of significant myeloid TFs such as *Gata1* were highly methylated in CLPs compared to CMPs. This study has demonstrated that the information from the combination of DNA methylation and gene expression data accurately inferred cellular identity of different blood cells, underscoring the value of DNA methylation in hematopoietic development (Bock et al., 2012).

For human hematopoiesis, a recent study provided genome-wide DNA methylation profile for HSPCs. This study used a nano *HpaII*-tiny-fragment-enrichment-by-ligation-mediated-PCR (nanoHELP) assay to investigate DNA methylation of long-term HSCs (LT-HSCs), short-term HSCs (ST-HSCs), CMPs, and MEPs. Loss of methylation has been observed when ST-HSC differentiated into CMPs, and methylation changes has been correlated with gene expression at this transition, while other commitments such as CMP to MEP transition did not show statistically significant correlation between DNA methylation and gene expression. These HSC commitment-associated methylation patterns were able to predict overall patient survival in three independent AML patient cohorts, indicating the importance of epigenetic regulation for normal hematopoietic development (Bartholdy et al., 2014). This thesis will compare our results of comprehensive methylome map of human hematopoiesis to the mouse studies and the human study.

3. AML and LSC

AML

AML is a genetically heterogeneous cancer of myeloid lineage blood cells, and characterized by an accumulation of immature myeloid lineage blood cells in bone marrow. Since AML is caused by diverse pathogenic mechanisms, it is very important to identify subgroups based on the different features of the disease such as morphology and genetic alterations (Lowenberg et al., 1999). The French-American-British (FAB) classification is the most common method to differentiate the heterogeneous disease based on the morphology of leukemic blasts, indicating the degree of differentiation (Table 1.1) (Bennett et al., 1976, 1985). Specific cytogenetic abnormalities such as translocations and chromosome rearrangements correlate with particular FAB subtypes (Table 1.1). These cytogenetic lesions have been used in prognosis to predict clinical outcomes and relapse rate (Table 1.2) (Byrd et al., 2002; Grimwade et al., 1998; Slovak et al., 2000). In addition to cytogenetic abnormalities, other genetic mutations play an important role in leukemogenesis, as about a half of AML cases do not harbor a cytogenetic lesion (Dohner, 2007; Lowenberg et al., 1999). The Cancer Genome Atlas (TCGA) has provided a public resource of genomic map of over 200 AML patients by performing either whole-genome sequencing or whole-exome sequencing. This comprehensive sequencing for a large cohort of AML patients revealed the mutational landscape of AML. Interestingly, AML genomes have relatively fewer genetic mutations compared to other solid tumors, 13 mutations on average, with only 5 in genes recurrently mutated in AML. Genetic alterations were classified to nine different categories based on their biological functions of genes harboring the alterations: TF fusions (18% of cases), NPM1 mutation (27%), tumor suppressors (16%), DNA methylation enzymes (44%), activated signaling genes (59%), myeloid TFs (22%),

chromatin modifiers (30%), cohesion-complex genes (13%) and spliceosome-complex genes (14%). TF-fusion includes PML-RARA, MYH11-CBFB, RUNX1-RUNX1T1, and PICALM-MLLT10; TP53, WT1, and PHF6 for tumor suppressors; DNMT3A, DNMT3B, DNMT1, TET1, TET2, IDH1, and IDH2 for DNA methylation enzymes; FLT3, KIT, KRAS/NRAS, PTPs, and other Tyr or Ser-Thr kinases; RUNX1, CEBPA, and other myeloid TFs for myeloid TFs; MLL-X fusions, MLL-PTD, NUP98-NSD1, ASXL1, EZH2, KDM6A, and other modifiers for chromatin modifying enzymes. This study has suggested common mutations such as DNMT3A, NPM1, CEBPA, IDH1/2 and RUNX1, which were mutually exclusive to TF-fusion might be involved in the initiation of AML (Cancer Genome Atlas Research, 2013).

LSC model

LSC model postulates that AML is organized as a hierarchy like normal hematopoiesis, in which LSCs give rise to leukemic blast cells like HSCs give rise to normal progenitors and differentiated cells. In the 1990s, Dick's group identified that a small subset of CD34⁺CD38⁻ cells were uniquely able to transplant AML into immune deficient mice (Bonnet and Dick, 1997; Lapidot et al., 1994). These observations lead to the hypothesis that LSCs possess increased self-renewal capacity, which enables LSCs to maintain and propagate the disease by generating bulk cancer cells (Kreso and Dick, 2014). Later, improved xenotransplantation models have revealed that LSC activity can be identified in other subpopulations as well such as CD34⁺CD38⁺ or CD34⁻ (Eppert et al., 2011; Goardon et al., 2011; Martelli et al., 2010; Sarry et al., 2011; Taussig et al.,

2008; Taussig et al., 2010). Recently, surface makers other than CD34 and CD38 were identified to enrich for LSCs among heterogeneous cells. C-type lectin-like molecule-1 (CLL-1) was expressed in one third of CD34+CD38- compartment of 29 AML patients (van Rhenen et al., 2007). CD96 was highly expressed in CD34+CD38- compartment of about two thirds of AML patients (Hosen et al., 2007). T-cell Ig mucin-3 (TIM3), was elevated in LSC fraction compared to normal HSCs (Jan et al., 2011; Kikushige et al., 2010). CD47 was highly expressed in LSC, and expression of it protected LSCs from being phagocytosed by macrophages (Majeti et al., 2009b). CD25 and CD32 were also identified as novel marker for LSCs (Saito et al., 2010). Even though, many studies have reported a variety of surface markers for LSC, heterogeneous expression of these markers in patients suggests a complex immunophenotype that cannot be applied universally in AML.

Recently, several studies have investigated genome-wide gene expression profiles of LSCs compared to HSCs or leukemia progenitor cells (LPCs) (de Jonge et al., 2011; Eppert et al., 2011; Gentles et al., 2010; Majeti et al., 2009a). Majeti et al. performed the first genome-wide gene expression analysis of LSCs compared with HSCs. They identified 3005 differentially expressed genes, enriched in pathways such as Wnt signaling, MAP kinase signaling, adherence junction, ribosome, and T cell receptor signaling (Majeti et al., 2009a). Gentles et al. identified 52 genes which distinguished CD34+CD38- LSCs from CD34+CD38+ LPCs through genome-wide gene expression analysis. This study showed 52 genes which were associated with overall, event-free, and relapse-free survival and with therapeutic response (Gentles et al., 2010). De Jonge et al. compared CD34+ fractions with the CD34- subfraction of AML patients and CD34+

normal progenitor compartment, and found that the top 50 CD34+ specific genes were able to predict overall survival of AML patients (de Jonge et al., 2011). These studies used the cell surface markers CD34 and CD38 to define LSC compartment, following the traditional LSC model. Eppert et al. have defined LSCs functionally using a xenograft assay. They sorted AML cells into 4 different fractions based on CD34 and CD38 expression first, then performed a xenograft assay on these fractions from 16 AML patients. They compared the gene expression profile of the functionally validated LSC to non-LSC or HSCs. The analysis demonstrated that LSC and HSC share a core transcriptional program, indicating the commonality between the two populations would be derived from ‘stemness’ property. The genes related to the stemness were associated with clinical outcome (Eppert et al., 2011).

Cell of origin

A number of both mouse and human studies have investigated the cell of origin in AML. Mouse studies have typically utilized retroviral oncogene transduction or knock-in models to explore this question and have generally led to the conclusion that committed progenitors, in particular CMP and/or GMP, serve as the cell of origin for most AML models. In one study of MN1-induced AML, retroviral transduction of single CMP, but not GMP or HSC, resulted in the development of AML, indicating tight restriction of transformation by this oncogene (Heuser et al., 2011). In a second study using a mouse model of MLL-AF9 AML, the cell of origin influenced biological properties such as gene expression, epigenetics, and drug responses (Krivtsov et al., 2013). Both of these studies

highlight the significance of this question for leukemogenesis and potential therapies. In contrast to mouse models, inferring the cell of origin in human leukemia is only possible based on features of the disease. Studies investigating the cell of origin of human AML using surface immunophenotype and gene expression originally suggested AML LSC arise from HSC (Kreso and Dick, 2014). However, a more recent study that compared genome-wide gene expression and surface markers of LSCs to those of normal HSPCs suggests that LSCs arise from more committed progenitors, including L-MPP and GMP (Goardon et al., 2011). In blast-crisis chronic myeloid leukemia (CML), GMPs with activation of beta-catenin from patients showed increased self-renewal and leukemogenic potential (Jamieson et al., 2004). Notably, three studies have recently reported that leukemogenic mutations existed in HSC, called ‘pre-leukemic HSC’ that underwent further clonal evolution to give rise to AML LSC. These studies have demonstrated a hierarchy among genetic mutations during clonal evolution of the pre-leukemic HSCs. For example, mutations in epigenome modifying enzymes such as DNMT3A, IDH1/2 have occurred earlier than mutations of genes involved in activated signaling such as FLT3 and NPM1 (Corces-Zimmerman et al., 2014; Jan et al., 2012; Shlush et al., 2014). These two studies suggest that the pre-leukemic HSCs which harbor the early occurring genetic mutations is a cell of origin in AML, which may lead to disease relapse after remission.

4. DNA methylation in AML

Somatic mutations in epigenome modifying enzymes in AML

Dysregulation of the epigenome is a common feature in AML, as indicated by the recent discoveries that a number of epigenome modifying genes are mutated in AML. These genes include several involved in the regulation of DNA methylation such as IDH1/2, DNMT3A, and TET2, and modulation of chromatin modifications such as ASXL1, EZH2, and others (Abdel-Wahab et al., 2012; Cancer Genome Atlas Research, 2013; Ley et al., 2010; Yan et al., 2011). Beyond somatic mutations in these epigenome modifying factors, characterization of DNA methylation in bulk AML cells has revealed great heterogeneity among patient cases. Figueroa et al. examined ~350 AML patient samples using HpaII tiny fragment enrichment by ligation-mediated PCR (HELP) interrogating ~14000 unique gene loci. This study identified 16 distinct clusters among the patients based on DNA methylation profile, which some of the clusters were associated with particular genetic aberrations such as mutations in CEBPA, NPM1, AML1-ETO, CBFb-MYH11, and PML-RARA (Figueroa et al., 2010b). This study showed the first epigenetically distinct subtypes in AML, associated with genetic alterations. However, this study was done before genetic mutations in epigenetic modifiers were identified. The mutations in epigenome modifying enzymes induce aberrant methylation in the AML cells. In particular, AML with IDH1 or IDH2 mutations was associated with globally increased DNA methylation (Cancer Genome Atlas Research, 2013; Figueroa et al., 2010a). MLL fusion or mutations in NPM1, DNMT3A, or FLT3 were associated with decreased DNA methylation. It is interesting to observe that about a half of AML patients (44%) harbored a genetic mutation in DNA methylation enzymes, suggesting a critical role of this process in leukemogenesis (Cancer Genome Atlas Research, 2013). Recent studies have investigated how genetic mutations

in DNA methylation enzymes play an important role in leukemic transformation. Challen et al. has shown loss of function of DNMT3A disturbed HSC differentiation over serial transplantation, while the LT-HSC compartment expanded (Challen et al., 2012). DNMT3A mutations have been associated with overexpression of HSC specific genes, such as HOXA and HOXB genes in AML patients (Yan et al., 2011). As mentioned previously, TET enzymes are known to be involved in DNA demethylation by producing 5hmC intermediates. It has been reported that bone marrow samples from patients with myeloid malignancies with TET2 mutations showed decreased 5hmC with hypomethylation compared to normal controls, and the interruption of TET2 function in mouse model has displayed myeloid-skewed differentiation of HSCs. (Ko et al., 2010; Moran-Crusio et al., 2011; Quivoron et al., 2011). TET2 mutation has been implicated in clonal hematopoiesis in elderly individuals (Busque et al., 2012; Genovese et al., 2014; Jaiswal et al., 2014; Xie et al., 2014). Several studies identified recurrent mutations in IDH1 and IDH2 in AML patients and their function in leukemogenesis (Figuerola et al., 2010a; Marcucci et al., 2010; Mardis et al., 2009; Ward et al., 2010). IDH1/IDH2 mutations displayed a neomorphic enzymatic activity generating 2-hydroxyglutarate (2-HG) from α -ketoglutarate (Dang et al., 2009; Ward et al., 2010). 2-HG, oncometabolite, has been shown to inhibit TET enzyme activity, and induce promoter hypermethylation (Figuerola et al., 2010a; Shih et al., 2012). All the studies have demonstrated the significant role of the DNA methylation enzymes in regulation of epigenome in hematopoietic differentiation and disease development.

Genetic mutations in chromatin modifying enzymes play a significant role in leukemogenesis. For example, loss of function mutations of ASXL1 causes a genome-

wide loss of H3K27me3 and collaborates with oncogenes to promote leukemogenesis (Abdel-Wahab et al., 2012). The role of EZH2 mutation in myeloid malignancies is complicated, as both loss of function and gain of function mutations in EZH2, a histone lysine methyltransferase and a member of a PRC2 complex have been implicated in leukemogenesis (Ernst et al., 2010; Lund et al., 2014)

Clinical implication of epigenetics in AML patients

Mutations in DNMT3A, IDH1, IDH2, and TET2 have been linked to clinical prognosis such as risk stratification and therapeutic responses in AML patients (Shih et al., 2012). DNMT3A mutation has been associated with adverse overall survival in intermediate-risk group patients (Ley et al., 2010; Patel et al., 2012). TET2 mutation has shown adverse overall survival in AML patients with intermediate-risk, while IDH1 or IDH2 mutation, which frequently co-occurred with NPM1 mutations, has shown favorable clinical outcome (Patel et al., 2012).

In addition to the association of genetic mutation in DNA methylation enzymes with clinical outcome, DNA methylation itself has been indicated as a prognostic marker. Figueroa et al. showed an association of distinct methylation clusters of AML patients to overall survival and demonstrated that 15 genes with aberrant DNA methylation could predict overall survival of AML patients (Figueroa et al., 2010b). Furthermore, quantitative DNA methylation has successfully predicted clinical outcome in AML patients (Bullinger et al., 2010). Deneberg et al. has reported that hypermethylation at polycomb group (PcG) target genes was associated with favorable clinical outcome in cytogenetically normal AML (CN-AML) (Deneberg et al., 2011).

Besides the prognostic power of DNA methylation, the alteration of DNA methylome of myeloid malignancies has been a target of therapy, as it is reversible. Azacitidine and decitabine, DNMT inhibitors, are widely used to improve clinical outcome in AML (Estey, 2013). Recent studies have reported that drugs regulating chromatin modification could be an effective therapy for AML patients. For example, suppression of bromodomain-containing 4 (BRD4), which recognizes acetylated lysine on histone, by the small molecule inhibitor, JQ1, demonstrated anti-leukemic effects (Valent and Zuber, 2014; Zuber et al., 2011). Small molecule inhibitors of DOT1L, a telomeric silencing 1-like histone 3 lysine 79 (H3K79) methyltransferase, have shown therapeutic effects against MLL-fusion AML (Daigle et al., 2013; Daigle et al., 2011). The epigenetic therapy is an active area of research and clinical trials for AML patients.

Chapter2

Epigenetic signature of leukemia stem cell

This work is an ongoing project of the Feinberg Lab and Johns Hopkins. All publication rights are reserved for these institutions and the presentation of this work here does not preclude future publication elsewhere.

Summary

AML is a hematopoietic malignancy, composed of a hierarchy that LSCs give rise into Blast cells. Since LSC is clonally related to Blasts, we hypothesized that particular epigenetic features would endow the distinct capacity of LSC, which can initiate and propagate the disease. Here, we first demonstrated epigenetic differences between LSCs and Blasts by performing genome-wide methylation analysis. We identified 84 DMRs in 70 genes, so called LSC epigenetic signature, which have shown differential methylation and expression. We found that *HOXA* cluster genes were enriched in LSC epigenetic signature, suggesting a critical role of these genes to confer the unique ability of LSC. The LSC epigenetic signature was partially dependent on genetic mutation in upstream regulators and epigenome modifying enzymes, yet about a half of it was independent of genetic mutation. The LSC epigenetic signature showed prognostic power in both DNA methylation and gene expression data sets, independent of previously known clinical factors such as age. These results provide the first evidence for epigenetic variation between LSC and their blast progeny in AML, and moreover, demonstrate that DMRs define prognostic subgroups of AML.

Results

AML LSC and Blasts Exhibit Epigenetic Differences That Define an LSC Epigenetic Signature

To formally investigate epigenetic differences between LSC and blast progeny, we sought to identify DMRs between functionally-defined AML LSC-enriched populations and their downstream non-engrafting blasts from a cohort of 15 primary patient samples. We obtained samples from 15 AML patients (Tables 2.1 and 2.2) and isolated subpopulations based on the expression of CD34 and CD38 including: Lin-CD34⁺CD38⁻, Lin-CD34⁺CD38⁺, and Lin-CD34⁻ (Figure 2.1). We then performed comprehensive genome-scale DNA methylation analysis using the Illumina Infinium HumanMethylation450 bead chip array. While AML LSC were originally described to be exclusively contained in the CD34⁺CD38⁻ subpopulation, recent reports have indicated that leukemia-initiating cells can also be detected in multiple compartments including both the CD34⁺CD38⁺ and CD34⁻ subpopulations, although usually at lower frequencies (Eppert et al., 2011; Goardon et al., 2011; Sarry et al., 2011).

In order to identify LSC and blast populations, we conducted xenotransplantation assays on all three CD34/CD38 subpopulations from each of the 15 AML cases (Table 2.3). Similar to other reports, leukemic engraftment was observed from at least one subpopulation in 10 out of 15 AML patients. As expected, LSC activity dramatically decreased following the immunophenotypic hierarchy with 64.3% of CD34⁺CD38⁻, 46.7% of CD34⁺CD38⁺, and 26.7% of CD34⁻ subpopulations engrafting *in vivo* (Table 2.3). To identify epigenetic markers of functional LSC, we performed DMR analysis between the 20 LSC-containing (engrafting) and 24 blast-containing (non-engrafting) fractions (hereafter termed “LSC” and “Blast”). The analysis identified 3030 DMRs, of

which 91.4% were hypomethylated in LSC (Table 2.4, see Appendix1 and Table 2.5). These DMRs were further classified according to their global genomic location including: islands (regions with a GC content greater than 50% and an observed/expected CpG ratio of more than 0.6), shores (regions within 2kb of an island), shelves (regions 2 to 4kb away from an island), and open sea (isolated CpG sites in the genome without a specific designation). These DMRs were nearly evenly distributed in CpG islands (27.8%) and open seas (29%), (Table 2.5). In addition, the DMRs strongly correlated with gene expression at CpG islands and open seas, whereas most hypomethylated DMRs in the engrafting populations were associated with transcriptional up-regulation of associated genes (Figure 2.2).

We next sought to integrate DNA methylation with gene expression analysis to identify an LSC epigenetic signature by extracting genes which passed a DMR p value <0.01 cutoff and exhibited >0.5 \log_2 fold gene expression change between the LSC and Blast populations, with an inverse relationship between gene expression and DNA methylation within 2kb of the transcriptional start site (TSS). We excluded gene body DMRs, as there was no statistically significant positive correlation in AML or normal hematopoiesis comparisons (Figure 2.3). We applied a minimum absolute value \log_2 0.5 fold gene expression cutoff, similarly to our previous LSC gene expression signature using the same microarray platform (Gentles et al., 2010). With these parameters, we identified 84 regions of 70 unique genes exhibiting differential methylation and gene expression in LSC compared to Blasts (Table 2.6).

We compared our LSC epigenetic signature to the LSC gene expression signatures from previous studies (Eppert et al., 2011; Gentles et al., 2010). Only six out

of 70 genes were found in these earlier studies, suggesting most of the genes identified here comprise a novel signature for LSC defined first by DMR analysis and refined by gene expression differences. One gene in this signature, *REC8*, which encodes a kleisin family protein that is associated with the cohesin complex, was hypomethylated and transcriptionally up-regulated in LSC (Figure 2.4a and Table 2.6). Notably, mutations of components of the cohesin complex have been identified in AML and other tumor types (Losada, 2014; Thol et al., 2014). We speculate that hypomethylation and increased expression of *REC8* in LSC might be related to cohesin complex activity in LSC. We also identified *HOXA5*, *HOXA6*, *HOXA7*, *HOXA9*, and *HOXA10* in the LSC epigenetic signature (Figure 2.4b-d and Table 2.6). These *HOXA* cluster genes were hypomethylated and highly expressed in LSC (Table 2.6). Notably, *HOXA9* showed hypomethylation and increased expression in LSC (Figure 2.4b and Table 2.6), and aberrant expression of *HOXA9* is known to be involved in increased proliferation of HSPCs and leukemogenesis, suggesting a critical role in LSC activity (Chung et al., 2006; Lehnertz et al., 2014; Takeda et al., 2006; Thorsteinsdottir et al., 2002).

Because the MLL subtype is itself associated with changes in expression of members of the *HOXA* gene cluster (Drabkin et al., 2002; Milne et al., 2002), we performed a second DMR analysis excluding the 5 LSC populations from the 2 MLL patients in our cohort. We observed substantial overlap between the sets of DMRs without MLL cases and with all samples. For the key LSC epigenetic signature, 81 of 84 DMRs, including the *HOXA* genes, were present after removal of the MLL cases (Table 2.7). Considering all DMRs with $p < 0.01$ (not just the LSC signature), there was 77%

overlap (Table 2.7). Thus, the presence of the MLL subtype was not a confounding variable in defining the LSC epigenetic signature.

The LSC Epigenetic Signature is Partially Dependent on Underlying Somatic Mutations

In order to identify important pathways and upstream regulators of LSC activity, we utilized Ingenuity Pathway Analysis (IPA). The most significantly enriched pathway was fatty acid α oxidation (Table 2.8), and inhibitors of this pathway have been previously shown to induce apoptosis of leukemia cells (Samudio et al., 2010). Ingenuity upstream regulator analysis identified *NPM1*, *ASXL1*, and *KAT6A* as the most significant upstream regulators of the LSC epigenetic signature genes, primarily through regulation of *HOXA* genes including *HOXA5*, *HOXA6*, *HOXA7*, *HOXA9*, and *HOXA10* (Table 2.9). Significantly, all three of these upstream regulators have been found to be mutated in AML and likely serve as driver genes (Cancer Genome Atlas Research, 2013). In particular, mutations in *ASXL1* and *NPM1* have been shown to cooperate with HOX genes to initiate leukemia by enhancing self-renewal and proliferation of hematopoietic progenitors (Abdel-Wahab et al., 2012; Vassiliou et al., 2011). Consistent with this, we observed that *NPM1* mutation was associated with decreased methylation and increased expression of *HOXA5*, *HOXA6*, *HOXA7*, *HOXA9*, and *HOXA10* compared to *NPM1* wild-type samples in the TCGA cohort (Figure 2.5).

We then sought to investigate the LSC epigenetic signature for its association with AML mutations in the TCGA cohort (Figure 2.6). The TCGA cohort consists of 200 AML patient samples with associated DNA methylation, gene expression, and full genotyping from genome/exome sequencing (Cancer Genome Atlas Research, 2013).

First, we identified the epigenetic signatures associated with individual AML mutations by performing DMR analysis between wild-type and mutant patient samples (Figure 2.6). The mutations tested included epigenome modifying enzymes such as *DNMT3A*, *IDH1/2*, and *TET1/2*, and upstream regulators of our LSC epigenetic signature, *NPM1* and *ASXL1* (Figure 2.6). *KAT6A* was not included as there was no patient who had this mutation among the patients investigated on methylation arrays. Next, we examined the overlap between the mutation-associated DMRs and our LSC epigenetic signature (Figure 2.6). Each LSC epigenetic signature gene was classified into three categories: (1) *upstream regulator-associated* if differentially methylated in association with any mutation in upstream regulators; (2) *epigenome modifying enzyme-associated* if differentially methylated in association with any mutation in epigenetic enzymes; or (3) *mutation-independent* if it was not differentially methylated in association with either upstream regulator or epigenome modifying enzyme (Figure 2.6 and Table 2.10). Of the 84 LSC DMRs, 28 (33.3%) and 27 (32.1%) were associated with upstream regulator or epigenome modifying enzyme mutations, respectively (Figure 2.6 and Table 2.10). However, 40 DMRs (47.6%) including *HOXA7* and *HOXA9* were mutation-independent targets (Figure 2.6 and Table 2.10). It should be noted that some of the LSC differentially methylated genes, including *HOXA7* and *HOXA9*, have multiple DMRs regulated by different mechanisms. For example, *HOXA7* has 4 DMRs in the LSC epigenetic signature; one associated with mutation in *NPM1*, two associated with mutation in *DNMT3A*, *TET1*, and *NPM1*, and one mutation-independent (Table 2.10). Therefore, we annotated each DMR in those genes differently with DMR numbering such as *HOXA9/DMR1* (Figure 2.6 and Table 2.10). A small subset (11 signatures) of upstream

regulator and epigenetic enzyme associated LSC epigenetic signatures overlapped, including *REC8*, *HOXA6*, and *HOXA7* (Figure 2.6 and Table 2.10). This analysis showed that all the *HOXA* genes are epigenetically regulated by at least one upstream regulator, and *HOXA6*, *HOXA7/DMR2*, and *HOXA7/DMR3* are common targets of both upstream regulators and epigenetic enzymes (Figure 2.6 and Table 2.10), and all of these changes involved DNA hypomethylation. In addition, hypomethylation of *HOXA7/DMR1* occurred independently of mutations (Figure 2.6 and Table 2.10). Together, these results suggest that overexpression of *HOXA* genes mediated by DNA hypomethylation is a core mechanism for LSC activity.

The LSC Epigenetic Signature is Associated with Overall Survival in Human AML

We hypothesized that if the LSC epigenetic signature reflected key drivers of the functional differences between LSC and Blasts, then this signature should be associated with clinical outcomes in human AML. First, we tested the association between the LSC epigenetic signature and overall survival in the DNA methylation data from the TCGA AML cohort (Cancer Genome Atlas Research, 2013). To assign each TCGA patient to an LSC-like or Blast-like category, we calculated scores of each TCGA sample based on the probability of being closer to either LSC or Blasts. A comparable number of samples were assigned to each category by this method (99 for Blast-like and 93 for LSC-like). In univariate survival analysis, the LSC-like group showed worse outcome compared to the Blast-like group (hazard ratio (HR) =2.3, (95% confidence interval (CI) =1.6-3.4); $p=1.07 \times 10^{-5}$) (Figure 2.7a). The LSC-like vs Blast-like stratification remained associated with overall survival in multivariate analysis together with other known prognostic factors such as age (considered as a continuous variable), cytogenetic risk (assessed as

high vs low risk and intermediate vs low risk), *NPM1*, and *FLT3* mutations (HR=1.9, (95% CI= 1.2-2.9); $p=0.003$; Table 2.11).

Next, we tested the association between expression of LSC epigenetic signature genes and clinical outcome using four different cohorts including TCGA (Cancer Genome Atlas Research, 2013), a cohort of normal karyotype patients (Dufour et al., 2010; Metzeler et al., 2008), and two cohorts of mixed karyotype patients (Valk et al., 2004; Wilson et al., 2006; Wouters et al., 2009). These cohorts consist of a total of 776 AML patients treated on different clinical protocols that also exhibited distinct biological characteristics (Gentles et al., 2010). We observed a strong correlation between the relative expression of LSC epigenetic signature genes and overall survival in the TCGA cohort (correlation=0.49; $p=4 \times 10^{-13}$; Figure 2.8). The more highly expressed a gene was in LSC compared to Blasts, the more robust its association with worse overall survival. In all four cohorts, the overall expression level of the signature genes was significantly associated with overall survival, with higher expression associated with worse clinical (Table 2.12). This association remained significant in multivariate Cox regression including age (continuous), cytogenetic risk, *NPM1*, and *FLT3* mutations (HR=1.7, (95% CI, 1.0-2.7); $p=0.03$; Table 2.11). Similar results were observed for the three other cohorts in univariate and multivariate analyses (Figures 2.7c-e, Tables 2.12 and 2.13).

Finally, we tested if mutations in epigenetic enzymes such as *DNMT3A*, *IDH1/2*, *TET2*, and *ASXL1* affected the prognostic impact of the LSC epigenetic signature in the TCGA cohort. As described previously, mutation in *DNMT3A*, but none of the other genes, was associated with patient overall survival (Table 2.14). Multivariate survival analysis including *DNMT3A* mutation showed that our LSC epigenetic signature

remained independently associated with clinical outcome in both the DNA methylation and gene expression data from TCGA, even when incorporating cytogenetic risk group (Table 2.15), as well as within the intermediate cytogenetic risk group alone (Table 2.16). Overall, these results demonstrate that the LSC epigenetic signature defined by DNA methylation and gene expression is associated with overall survival in human AML.

Discussion

The cancer stem cell (CSC) model was originally proposed based on observations from human AML in which only subpopulations of leukemia-initiating or LSC possessed engraftment potential (Bonnet and Dick, 1997; Lapidot et al., 1994). According to this model, the LSC give rise to downstream Blasts that lack critical stem cell properties. As LSC and their non-engrafting Blast progeny are clonally related, a major implication of this leukemia stem cell model is that their functional properties must be due to epigenetic differences. Here, we provide such evidence by characterizing global DNA methylation features of LSC defined by xenotransplantation of AML subpopulations, compared to non-engrafting Blast cells, demonstrating that AML LSC exhibit global hypomethylation compared to non-LSC Blast cells. Integrating DNA methylation and gene expression analysis, we identified 84 regions of 70 genes as the LSC epigenetic signature. 64 of these 70 genes were not reported in previous gene expression studies for LSC (the exceptions being *CD34*, *SH3BP5*, *BPMS*, *LTB*, *MS4A3*, and *VNN1*) (Eppert et al., 2011; Gentles et al., 2010). Most of the LSC epigenetic signature was *mutation-independent*, not associated with mutations in upstream regulators or epigenome-modifying enzymes suggesting that leukemogenesis may converge on these primary epigenetic signatures We

also identified some *mutation-associated* epigenetically dysregulated genes, including *REC8* and *HOXA7*. Together, these epigenetic signatures represent potential therapeutic targets regardless of the different types of the underlying mutations present in individual AML cases. Furthermore, the LSC epigenetic signature was prognostic of patient overall survival independently of known survival predictors such as age and cytogenetic abnormalities, emphasizing its functional importance.

Apart from its prognostic effect, the LSC epigenetic signature represents a molecular target that may improve patient survival and prevent relapse. Recently, epigenetic therapy with hypomethylating agents azacytidine and decitabine has been approved for the treatment of AML. Randomized trials demonstrated improved overall survival compared to chemotherapy, but also indicated limited effect on relapse rate in high-risk AML (Estey, 2013). Our results indicate that LSC are relatively hypomethylated compared to Blasts, suggesting that they may be less effectively targeted by hypomethylating agents, possibly accounting for their limited efficacy in relapse-free survival. It would be of great interest to see how the LSC epigenetic signature is affected by these drugs.

More specifically, this LSC epigenetic signature was markedly enriched for members of the *HOXA* cluster, suggesting this cluster is a key driver of LSC function. The *HOXA* cluster has been implicated as a key regulator of hematopoiesis and myeloid malignancy (Alharbi et al., 2013). In particular, *HOXA9* is known to be involved in increased proliferation of HSPC and leukemogenesis (Thorsteinsdottir et al., 2002), even occurring as a fusion oncogene in rare cases (Nakamura et al., 1996). Moreover, increased expression of *HOXA9* has been found to be an adverse prognostic factor in

AML (Golub et al., 1999). Other *HOXA* family members including posterior (*HOXA7*, *HOXA9*, and *HOXA10*) and anterior (*HOXA6*) members have been implicated in leukemogenesis, as overexpression of these genes in normal mouse HSPC leads to increased self-renewal, transformation, and development of myeloid malignancies (Bach et al., 2010). The functional LSC epigenetic signature provided here demonstrates that the *HOXA* family is a key driver of AML LSC that may function in imparting aberrant self-renewal.

Materials and Methods

Human Samples

Human acute myeloid leukemia (AML) samples were collected from patient peripheral blood (PB) or bone marrow (BM) at Stanford hospital, according to an IRB-approved protocol (22264), and informed consent was obtained from all subjects. PBMC or BMMC were separated with Ficoll-Paque Plus (Amersham Biosciences, Piscataway, NJ, Catalog number: 17-1440-03), and cryopreserved in 1 x freezing medium (90%FBS + 10%DMSO). All the AML experiments were conducted with cryopreserved PBMC or BMMC samples that were thawed and washed in IMDM medium containing 10% FBS.

Flow Cytometry Analysis and Cell Sorting

A battery of antibodies (Abs) was used for staining, analysis and sorting of progenitor cells from AML patient PBMCs/BMMCs, as well as lineage analysis human chimerism/engraftment (Table 2.17). Cells were either analyzed or sorted using a FACS Aria II cytometer (BD Biosciences, Franklin Lakes, NJ). Analysis of flow cytometry raw data was done with FlowJo Software (Treestar, Ashland, OR).

Xenotransplantation Assay

NOD.Cg-*Prkdc*^{scid} *Il2rg*^{tm1Wjl}/SzJ mice (NSG) were obtained from The Jackson Laboratory (Bar Harbor, ME) and bred in a specific pathogen-free environment per Stanford Administrative Panel on Laboratory Animal Care Guidelines (Protocol 22264). Six to eight week-old adult mice were exposed to 200 rads of gamma irradiation at least two hours (up to 24 hours) prior to transplantation. Up to 500 thousand fresh-sorted AML cell subpopulation were resuspended in 30 μ l of Hank's Balanced Salt Solution (HBSS) (Gibco Life Technologies, Grand Island, NY) containing 2% FBS, and injected intravenously via the tail vein using a 29-gauge needle. For each cell subpopulation, at least three technical replicates were performed by transplantation of three aliquot of cells into three mice. Around 150 mice in total were used. Neither randomization nor blinding was used for this study.

After eight weeks, mice were euthanized with CO₂ according to IRB approved protocol (22264). BM were isolated using scissors and needle flashing, then underwent hypotonic red cell lysis using ACK (Ammonium-Chloride-Potassium) lysing buffer (Life Technologies, Grand Island, NY, Catalog# A10492). BMMCs were stained with Ab combinations (Table 2.17) on ice for 30 minutes, and dead cells were excluded by propidium iodide (PI) staining. Human myeloid engraftment (hCD45+CD33+) and lymphoid engraftment (hCD45+CD19+) were analyzed on flow as described before.

Illumina Infinium Human Methylation 450 Bead Array Assay

Genomic DNA from each sample was purified using the MasterPure DNA purification kit (Epicentre) according to the manufacturer's protocol. The genomic DNA (250-500ng) was treated with sodium bisulfate using the Zymo EZ DNA Methylation Kit (ZYMO

Research) as recommended by the manufacturer, with the alternative incubation conditions for the Illumina Infinium Methylation Assay. Converted DNA was eluted in 11ul of elution buffer. DNA methylation level was measured using Illumina Infinium HD Methylation Assay (Illumina) according to the manufacturer's specifications. Methylation array data are deposited at the Gene Expression Omnibus (GEO) with accession number GSE63409.

Illumina Infinium Human Methylation 450 Bead Array Analysis

Raw intensity files were obtained using minfi package (Aryee et al., 2014) to calculate methylation ratios (Beta values). The data was normalized using Illumina preprocessing method implemented in minfi. Several quality control measures were applied to remove arrays with low quality. Control probes were examined on the 450k array to assess several measures including bisulfite conversion, extension, hybridization, specificity and others. Next, median methylated and unmethylated signals were calculated for each arrays; no array was identified for signal values lower than 10.5. For multidimensional scaling analysis, probes containing an annotated SNP (dbSNP137) at the single-base extension or CpG sites were removed (17398 probes removed). Minfi 1.8.9 was used.

Bump hunting method previously described was applied to identify DMRs in 450k array (Aryee et al., 2014; Jaffe et al., 2012). Beta value of 0.1 (10% of methylation difference) was used as cutoff when finding DMRs. Statistical significance was assigned by permutations testing and the P-value cutoff used for downstream analysis was <0.01 that corresponded to Benjamini-Hochberg adjusted p-value <0.1 (data not shown) unless different cutoff was designated in result part. Bumphunter 1.2.0 was used. Same method

was applied to identify DMRs for the second DMR analysis of LSC vs Blast that we removed 5 LSC cases from 2 MLL patients (SU042 and SU046).

Affymetrix Microarray Expression Analysis

Total RNA was extracted from each FACS-sorted cell population using RNeasy® Plus Mini (QIAGEN, Valencia, CA, Catalog#: 74134) according to the manufacture's protocol. All RNA samples were quantified with 2100 Bioanalyzer (Agilent Technologies, Santa Clara, CA), subjected to reverse transcription, two consecutive rounds of linear amplification, and production and fragmentation of biotinylated cRNA. 15µg of cRNA from each sample was hybridized to HG U133 Plus 2.0 microarrays. Hybridization and scanning were performed according to the manufacture's instruction (Affymetrix). This step was performed at the PAN center of Stanford University. Data were normalized by GC robust multi-array average method and analyzed on R/Bioconductor. SU042 CD34+38+ was removed from further analysis due to low quality. SU001 was excluded, as the samples from this patient were not included on expression array (GEO GSE63270).

Sanger Sequencing to Detect AML Mutations

Genomic DNA was extracted from patient BMMC or PBMC using QIAmp DNA Mini Kit (QIAGEN, Valencia, CA, Catalog#: 51304) according to the manufacture's instruction. PCR primers were designed to cover exon 3-11 of TET2, exon 4 of IDH1/2, and exon 7-23 of DNMT3A (Table 2.18). The PCR reaction premix consists of 1x of OneTaq 2x Master Mix (NEB, Ipswich, MA, Catalog#: M0482L), 0.2µM forward and reverse primers respectively, and 10ng (up to 100ng) genomic DNA as template. The reaction was under the condition of 95°C initial denaturation for 30 seconds, 45 cycles of

extension containing 94°C for 30 seconds, 56°C for 1 minute (or as necessary) and 72°C for 1 minute, and a final extension at 72°C 5 minutes. The PCR products were concentrated with PCR purification kit (QIAGEN, Valencia, CA, Catalog#: 28106), then submitted to Sequentech (Mountain View, CA) for sequencing of both forward and reverse directions using 3730xl DNA Analyzer (Applied Biosystems, Foster City, CA) according to the manufacturer's instruction. The sequencing data was analyzed using Sequencher 5.1 (Gene Codes Corporation, Ann Arbor, MI), and single-nucleotide polymorphism (SNP) was excluded by checking NCBI website before getting the final mutation results.

Survival Analysis

Survival analysis was performed to assess the association of LSC DNA methylation and gene expression signatures with clinical outcome (overall survival) in 4 different cohorts. For DNA methylation data set (TCGA), patients were separated into two groups; LSC-like and Blast-like based on the methylation profile of each individual. Survival was compared between the two groups using the *coxph* function in R (survival package 2.37), with significance assessed by log-rank test. For gene expression, the genes in the LSC epigenetic signature were identified in expression datasets for which survival outcomes were available. The first principal component of their expression levels was computed, and patients were stratified as “high” or “low” relative to its median value. Survival differences between the groups were assessed by log-rank test. In multivariate analyses, age was incorporated as a continuous variable, mutations were coded as present/absent (1/0), and assessment of cytogenetic risk was treated as individual groups and done for

intermediate vs low-risk and High vs low risk (Figure 2.9). Analysis was also performed within intermediate risk groups.

Statistical Analysis

To assign cell identity of LSC/Blast to TCGA samples, mean methylation value of each LSC epigenetic signature (84 DMRs) for LSC/Blast (methylation profile) was retrieved and standard deviation of the mean value for each signature was calculated. Then scores (probability density values as log value) for each TCGA sample regarding LSC and Blast profile was calculated using `dnorm` function with the mean and standard deviation calculated in previous step. Maximum value of scores between the ones regarding LSC and Blast methylation profile was chosen, and then cell identity assigned.

Bioinformatics Analysis

QIAGEN's Ingenuity IPA (Ingenuity® Systems, www.ingenuity.com) was performed for pathway analysis.

Figure 2.1. Pre-sort and post-sort FACS analysis of subpopulations from human AML. Top panel: FACS-sorting scheme of three immunophenotypically defined subpopulations from human AML samples. Other panels: Two rounds of post-sort analysis to check the purity of sorting.

Figure 2.2. Gene expression inversely correlates with DMRs at CpG island and open sea. Engrafting (LSC) and non-engrafting (blast) subpopulations from primary AML cases were profiled for DNA methylation and gene expression to identify differentially methylated regions (DMRs) and differentially expressed genes between these two groups. DMRs that are located within 2kb of gene transcriptional start sites (TSSs - black dots) were classified into 4 groups according to their distance relative to a CpG island: island, shore, shelf, and open sea. DMRs located further than 2kb away from TSSs are denoted as black pluses. Log₂ ratios of differential expression were plotted against differential methylation (all values are blast compared to LSC). Wilcoxon rank-sum tests were performed to test the null hypothesis that the expression differences for the hypo- or hypermethylated DMRs within 2kb of gene TSSs (black dots) showed stronger inverse correlation than the expression differences of the random DMRs that are located further than 2kb of TSSs (black pluses). Random DMRs were shown in the middles of DNA methylation axis regardless of their methylation differences.

b**HSC vs GMP****HSC vs MEP**

Figure 2.3. Gene body methylation doesn't show statistically significant positive correlation with gene expression. DMRs that are located in gene body (TSS to transcription end site (TES)) were classified into three groups according to their distance relative to a CpG island: island, shore, shelf/open sea. Random DMRs that don't locate in gene body are denoted as black pluses. Log₂ ratios of differential expression were plotted against differential methylation. Wilcoxon rank-sum tests were performed to test the null hypothesis that the expression differences for the hypo- or hypermethylated DMRs located in gene body (black dots) showed stronger positive correlation than the expression differences of the random DMRs that do not locate in gene body (black pluses). **(a)** LSC vs Blast. All values for DNA methylation and gene expression are from LSC-Blast. **(b)** Normal hematopoiesis. HSC vs GMP and HSC vs MEP are shown. All values for DNA methylation and gene expression are from group2 – group1 for group1 vs group2 comparisons.

Figure 2.4. AML LSC and Blasts exhibit epigenetic differences that define an LSC epigenetic signature. Plots of differentially methylated regions (DMRs) indicating genomic loci for *REC8* (a), *HOXA9* (b), *HOXA7* (c) and *HOXA10* (d), four LSC epigenetic signature genes that are hypomethylated and upregulated in LSC. Top: level of CpG methylation (beta) of each sample for the region; Middle: CpG density (curve), CpG sites (black tick marks), CpG islands (red lines); Bottom: gene annotation.

Figure 2.5. *NPM1* mutation is associated with decreased methylation and increased expression of *HOXA* genes. (a) Box plots show methylation level for *NPM1* mutants and wild-type samples for DMRs for *HOXA5*, *HOXA6*, *HOXA7*, *HOXA9*, and *HOXA10* in the TCGA dataset. t-test assuming unequal variance was performed to look at statistical significance of the association between *NPM1* mutation and methylation. DNA methylation of all the *HOXA* genes was significantly associated with *NPM1* mutation. (b) Box plots show gene expression (Log₂ value) for *NPM1* mutants and wild-type samples for *HOXA5*, *HOXA6*, *HOXA7*, *HOXA9*, and *HOXA10* in the TCGA dataset. t-test assuming unequal variance showed *NPM1* mutation highly correlated with increased expression of all the *HOXA* genes tested.

Figure 2.6. The LSC epigenetic signature is partially dependent on underlying somatic mutations. Shown is a schematic flow chart of mutation association analysis. We compared our LSC epigenetic signature to the mutation specific DMRs obtained from TCGA data set. The LSC epigenetic signature was classified into three different groups, and each DMR is shown in this diagram. Note that several genes such as *HOXA9* have multiple DMRs and different DMRs in one gene are annotated with DMR number such as *HOXA9/DMR1*.

Figure 2.7. The LSC epigenetic signature is associated with overall survival in human AML. (a) TCGA samples were classified as LSC-like or Blast-like based on DNA methylation alone by generating methylation profiles of the LSC and Blast populations, and then calculating scores of each sample based on the probability of being closer to either LSC or Blast. Kaplan-Meier survival analysis was then applied to these groups as indicated. Statistical significance was determined by the Log-rank test (n=192; 93 LSC-like and 99 Blast-like patients). (b-e) Expression of the LSC epigenetic signature genes was combined to create an LSC score, which was then calculated in AML samples from four independent cohorts including TCGA (n=182; 91 high and 91 low score patients) (b) Metzeler et al (n=163; 81 high and 82 low score patients) (c), Wouters et al (n=262; 131 high and 131 low score patients) (d), and Wilson et al (n=169, 84 high and 85 low score patients) (e). In each cohort, patients were classified into high and low groups based on the median value. Kaplan-Meier survival analysis was then applied to these groups as indicated. Statistical significance was determined by the Log-rank test.

Figure 2.8. The gene expression of the LSC epigenetic signature highly correlates with clinical outcome in the TCGA dataset. Each dot represents an LSC epigenetic signature gene. Survival z-score was plotted against log₂ ratio of differential expression of the LSC epigenetic signature genes in TCGA.

Table 2.7. Second DMR analysis to examine confounding effect of MLL cases

	LSC epigenetic signature	DMRs (p value<0.01)
All Samples	84	3030
No MLL cases	49	1398
Overlap	73.5% (36/49)	77% (1076/1398)

Table 2.8. Ingenuity pathway analysis

Ingenuity Canonical Pathways	-log(p-value)	Molecules
Fatty Acid α -oxidation	2.8E00	ALDH2,PTGS2
Melatonin Degradation III	1.81E00	MPO
Anandamide Degradation	1.81E00	FAAH
NRF2-mediated Oxidative Stress Response	1.73E00	GSTM5,MAFF,CBR1
VDR/RXR Activation	1.59E00	BGLAP,HOXA10
Eicosanoid Signaling	1.57E00	PTGS2,PTGER4
Phenylethylamine Degradation I	1.47E00	ALDH2
HGF Signaling	1.35E00	DOCK1,PTGS2
Prostanoid Biosynthesis	1.34E00	PTGS2
Parkinson's Signaling	1.31E00	SNCA
Corticotropin Releasing Hormone Signaling	1.25E00	PTGS2,GUCY1B3
Granzyme A Signaling	1.22E00	H1F0
Glutathione Redox Reactions I	1.12E00	CLIC2
Relaxin Signaling	1.12E00	RXFP1,GUCY1B3
Aryl Hydrocarbon Receptor Signaling	1.12E00	GSTM5,NFIA
Histamine Degradation	1.09E00	ALDH2
eNOS Signaling	1.08E00	LPAR6,GUCY1B3
Tryptophan Degradation X (Mammalian, via Tryptamine)	1.08E00	ALDH2

Oxidative Ethanol Degradation III	1.08E00	ALDH2
Putrescine Degradation III	1.06E00	ALDH2
Ethanol Degradation IV	1.06E00	ALDH2
Triacylglycerol Degradation	1.03E00	FAAH
Phenylalanine Degradation IV (Mammalian, via Side Chain)	1.02E00	ALDH2
Gap Junction Signaling	1.01E00	BGLAP,GUCY1B3
IL-9 Signaling	9.95E-01	SOCS2
MIF-mediated Glucocorticoid Regulation	9.83E-01	PTGS2
Role of JAK2 in Hormone-like Cytokine Signaling	9.83E-01	SOCS2
Dopamine Degradation	9.5E-01	ALDH2
Production of Nitric Oxide and Reactive Oxygen Species in Macrophages	9.39E-01	MPO,HOXA10
Inhibition of Angiogenesis by TSP1	9.39E-01	GUCY1B3
Glutathione-mediated Detoxification	9.39E-01	GSTM5
IL-8 Signaling	9.35E-01	MPO,PTGS2
Endothelin-1 Signaling	9.35E-01	PTGS2,GUCY1B3
Sertoli Cell-Sertoli Cell Junction Signaling	9.35E-01	MPP6,GUCY1B3
ILK Signaling	9.32E-01	DOCK1,PTGS2
Ethanol Degradation II	8.99E-01	ALDH2
MIF Regulation of Innate Immunity	8.9E-01	PTGS2
FcγRIIB Signaling in B Lymphocytes	8.81E-01	BLNK
Primary Immunodeficiency Signaling	8.23E-01	BLNK

Noradrenaline and Adrenaline Degradation	8.23E-01	ALDH2
Lymphotoxin β Receptor Signaling	7.93E-01	LTB
Role of IL-17A in Arthritis	7.93E-01	PTGS2
Nur77 Signaling in T Lymphocytes	7.79E-01	HDAC9
Huntington's Disease Signaling	7.74E-01	HDAC9,SNCA
Colorectal Cancer Metastasis Signaling	7.6E-01	PTGS2,PTGER4
Phototransduction Pathway	7.59E-01	GUCY1B3
Role of JAK1 and JAK3 in γ c Cytokine Signaling	7.46E-01	BLNK
Phospholipase C Signaling	7.43E-01	BLNK,HDAC9
Cell Cycle: G1/S Checkpoint Regulation	7.4E-01	HDAC9
CD40 Signaling	7.34E-01	PTGS2
Antiproliferative Role of Somatostatin Receptor 2	7.22E-01	GUCY1B3
Macropinocytosis Signaling	7.16E-01	RAB34
Role of MAPK Signaling in the Pathogenesis of Influenza	7E-01	PTGS2
IL-17 Signaling	6.94E-01	PTGS2
T Helper Cell Differentiation	6.94E-01	IL12RB2
JAK/Stat Signaling	6.94E-01	SOCS2
Glucocorticoid Receptor Signaling	6.92E-01	BGLAP,PTGS2
Growth Hormone Signaling	6.89E-01	SOCS2
Small Cell Lung Cancer Signaling	6.84E-01	PTGS2
STAT3 Pathway	6.84E-01	SOCS2

TREM1 Signaling	6.73E-01	MPO
Prolactin Signaling	6.73E-01	SOCS2
Cyclins and Cell Cycle Regulation	6.63E-01	HDAC9
Serotonin Degradation	6.63E-01	ALDH2
Superpathway of Melatonin Degradation	6.58E-01	MPO
ErbB Signaling	6.26E-01	EREG
Altered T Cell and B Cell Signaling in Rheumatoid Arthritis	6.17E-01	LTB
Crosstalk between Dendritic Cells and Natural Killer Cells	6.09E-01	LTB
FAK Signaling	6.09E-01	DOCK1
Neuregulin Signaling	5.97E-01	EREG
Chronic Myeloid Leukemia Signaling	5.97E-01	HDAC9
PPAR Signaling	5.93E-01	PTGS2
p53 Signaling	5.77E-01	HDAC9
Fcγ Receptor-mediated Phagocytosis in Macrophages and Monocytes	5.73E-01	DOCK1
Telomerase Signaling	5.73E-01	HDAC9
IGF-1 Signaling	5.73E-01	SOCS2
Paxillin Signaling	5.62E-01	DOCK1
Cholecystokinin/Gastrin-mediated Signaling	5.48E-01	PTGS2
Pancreatic Adenocarcinoma Signaling	5.41E-01	PTGS2
Type I Diabetes Mellitus Signaling	5.31E-01	SOCS2
Nitric Oxide Signaling in the Cardiovascular System	5.28E-01	GUCY1B3

Gas Signaling	5.25E-01	PTGER4
Hereditary Breast Cancer Signaling	5.12E-01	HDAC9
Gα12/13 Signaling	5.09E-01	LPAR6
14-3-3-mediated Signaling	5.06E-01	SNCA
RhoA Signaling	4.91E-01	LPAR6
LXR/RXR Activation	4.8E-01	PTGS2
PI3K/AKT Signaling	4.8E-01	PTGS2
Ovarian Cancer Signaling	4.67E-01	PTGS2
PI3K Signaling in B Lymphocytes	4.67E-01	BLNK
Sperm Motility	4.61E-01	GUCY1B3
Type II Diabetes Mellitus Signaling	4.54E-01	SOCS2
Protein Kinase A Signaling	4.53E-01	PTGS2,H1F0
IL-12 Signaling and Production in Macrophages	4.51E-01	IL12RB2
Cellular Effects of Sildenafil (Viagra)	4.44E-01	GUCY1B3
Synaptic Long Term Depression	4.23E-01	GUCY1B3
CXCR4 Signaling	4.03E-01	DOCK1
Axonal Guidance Signaling	3.99E-01	DOCK1,ROBO3
Acute Phase Response Signaling	3.81E-01	SOCS2
Dopamine-DARPP32 Feedback in cAMP Signaling	3.73E-01	GUCY1B3
Role of NFAT in Regulation of the Immune Response	3.7E-01	BLNK
Dendritic Cell Maturation	3.66E-01	LTB

B Cell Receptor Signaling	3.62E-01	BLNK
Role of NFAT in Cardiac Hypertrophy	3.54E-01	HDAC9
Calcium Signaling	3.54E-01	HDAC9
Mitochondrial Dysfunction	3.5E-01	SNCA
Agranulocyte Adhesion and Diapedesis	3.47E-01	CD34
ERK/MAPK Signaling	3.45E-01	DOCK1
mTOR Signaling	3.4E-01	DDIT4
Hepatic Fibrosis / Hepatic Stellate Cell Activation	3.29E-01	LTB
Integrin Signaling	3.27E-01	DOCK1
Actin Cytoskeleton Signaling	3E-01	DOCK1
cAMP-mediated signaling	2.97E-01	PTGER4
LPS/IL-1 Mediated Inhibition of RXR Function	2.96E-01	GSTM5
Role of Osteoblasts, Osteoclasts and Chondrocytes in Rheumatoid Arthritis	2.94E-01	BGLAP
G-Protein Coupled Receptor Signaling	2.48E-01	PTGER4
Xenobiotic Metabolism Signaling	2.38E-01	GSTM5
Role of Macrophages, Fibroblasts and Endothelial Cells in Rheumatoid Arthritis	2.1E-01	LTB

Table 2.9. Ingenuity upstream regulator analysis

Upstream Regulator	p-value of overlap	Target molecules in dataset
ASXL1	8.18E-12	HOXA10,HOXA5,HOXA6,HOXA7,HOXA9
KAT6A	4.16E-07	HOXA5,HOXA7,HOXA9
NPM1	1.09E-06	HOXA10,HOXA5,HOXA7,HOXA9
phorbol myristate acetate	1.88E-06	BGLAP,CD52,CRHBP,DDIT4,FAAH,HOXA5,HOXA7,HOXA9,IL12RB2,LTB,MPO,PTGER4,PTGS2
KMT2A	6.98E-06	HOXA10,HOXA5,HOXA7,HOXA9
raloxifene	8.44E-06	BGLAP,BLNK,DDIT4,LAMB2,MPPED2,PTGS2
nimesulide	1.38E-05	EREG,MPO,PTGS2
1-methyl-4-phenylpyridinium	1.66E-05	DDIT4,MPO,SNCA

Table 2.10. Association of LSC epigenetic signature with DMRs of genetic mutations

Columns are chromosome, start, end, diffMethyl(difference of methylation percentage for LSC-Blast), diffexp(difference of expression log2 value for LSC-Blast), Gene, DMR name, DNMT3A,IDH1,IDH2,TET2,NPM1,ASXL1(Genetic mutations tested here to look at overlap of LSC epigenetic signature and DMR for mutations), Mechanism(which mechanism regulate each DMR).

"1" represent overlap and "0" represents no overlap between the corresponding LSC epigenetic signature and DMRs for DNMT3A, IDH1, IDH2, TET2, NPM1 and ASXL1.

Gene	DMR name	DNMT3A	IDH1	IDH2	TET1	TET2	NPM1	ASXL1	Mechanism

Note: For IDH1 and IDH2, a single point mutation was tested in exon 4 (R132 and R140 respectively); for TET2 and DNMT3A mutations, multiple exons were tested based on regions of frequent somatic mutation according to COSMIC database (Wellcome Trust Sanger Institute).

Chapter 3

Epigenetic basis of human normal hematopoietic development

This work is an ongoing project of the Feinberg Lab and Johns Hopkins. All publication rights are reserved for these institutions and the presentation of this work here does not preclude future publication elsewhere.

Summary

DNA methylation plays an indispensable role during tissue development and cellular differentiation. Hematopoiesis is one of best-understood and characterized developmental processes. We hypothesized that DNA methylation would be an essential mechanism during lineage differentiation in human hematopoiesis. Here, we provide a comprehensive methylome map of HSPCs, particularly in myeloid lineage, by performing a genome-wide DNA methylation analysis. We found that DNA methylation distinguished distinct lineages of hematopoiesis, suggesting a critical role of it during hematopoietic development. In concordance with previous studies for tissue development, we observed that most of DNA methylation changes during hematopoietic differentiation occurred at non-CpG island regions such as CpG island shores or open seas. We identified DMRs in potential novel regulators of hematopoiesis including *HMHB1* and *MIR539*, as well as in previously known genes such as *MPO* and *CDK6*. The DMRs for normal hematopoiesis were enriched in a regulatory genomic element, super-enhancer. We found massive epigenetic variation between murine and human hematopoiesis, explaining the intrinsic differences during the hematopoietic development in those species.

Results

Comprehensive DNA Methylation Analysis Shows Tight Clustering of Human Hematopoietic Stem and Progenitor Cells

Human hematopoiesis proceeds through a series of multipotent and oligopotent stem and progenitor cells that progressively lose self-renewal ability and become more restricted in their differentiation potential (Figure 3.1). These critical functional properties are mediated in part through epigenetic mechanisms, including DNA methylation. We obtained bone marrow from five normal donors and isolated HSPC by fluorescence-activated cell sorting (FACS) including: hematopoietic stem cells (HSC), multipotent progenitors (MPP), L-MPP, common myeloid progenitors (CMP), megakaryocyte/erythroid progenitors (MEP), and GMP (Figure 3.2, Tables 3.1 and 3.2).

In order to further understand epigenetic variation during early human hematopoiesis, we generated genome-scale methylation profiles for normal hematopoietic stem and progenitor cell populations. Strikingly, multidimensional scaling analysis utilizing the top 1000 most variable CpG positions revealed tight clustering of human HSPC populations by lineage with no outliers (Figure 3.3). As the distance between clusters in multidimensional scaling is a measure of their similarity, this analysis indicates that DNA methylation reflects the function and hierarchy of the HSPC populations. For example, HSC and MPP clusters are close together reflecting their functional similarities. Similarly, L-MPP are located between HSC/MPP and GMP clusters, but farther away from MEP, supporting the hypothesis that L-MPP is an early lymphoid progenitor, which retains myeloid programs for GMP, but not MEP, differentiation (Doulatov et al., 2010; Goardon et al., 2011).

DMR Analysis Identified Previously Known and Novel Regulators in Human Hematopoietic Development

The DMRs identified across HSPC not only permit clustering of these populations, but also have the potential to reveal novel regulators of hematopoietic lineage development. We first examined the DMRs for genes already known to play such a role. The DMR analysis identified myeloperoxidase (*MPO*), a well-established protein involved in neutrophil activity (Klebanoff, 2005), which showed progressive hypomethylation going from HSC to GMP, but exhibited hypermethylation in MEP (Figure 3.4). Similarly, *CDK6*, a cyclin-dependent protein kinase important in hematopoietic cell differentiation (Kozar and Sicinski, 2005; Malumbres et al., 2004), was progressively hypermethylated during differentiation from HSC to MEP and GMP (Figure 3.4). In both cases, these results were confirmed through direct pyrosequencing of these loci (Figure 3.4), validating the DNA methylation array approach. In addition to these two examples, a number of genes known to be involved in early hematopoiesis were found to be differentially methylated including: *STAT3*, *KEL*, *IDH2*, *HLF*, *NOTCH1*, *GATA1*, and *HOX* family genes (Table 3.3, see Appendix2).

This analysis also identified novel sites of epigenetic variation during hematopoiesis. For example, *HMHB1*, encoding one of the minor histocompatibility antigens, was found to be hypomethylated in L-MPP and GMP, suggesting a possible role in GMP differentiation (Figure 3.5). Progressive hypomethylation was also identified in *MIR539* going from HSC to MEP, suggesting that this microRNA may contribute to erythropoiesis (Figure 3.5). Interestingly, the *MIR539* gene is located in DLK1-DIO3 imprinting region that contains a miRNA cluster involved in leukemia pathogenesis

(Benetatos et al., 2013). Further validation of these novel candidate regulators will require functional experiments.

We next sought to classify the DMRs among normal HSPCs according to their global genomic location in islands, shores, shelves, and open seas. Focusing on the comparison of HSC with GMP, we found that most DMRs were not in CpG islands, but were enriched outside of the islands, predominantly in shelves and open seas, compared to the distribution of random length matched DMRs (Figure 3.6a). The comparison of HSC with MEP also showed enrichment of DMRs at non-CpG island regions such as shores, shelves, and open seas (Figure 3.6b). Similarly, genes with an inverse correlation between DNA methylation and gene expression were located outside of the islands themselves, with the strongest correlation at shores and open seas for both comparisons (Figure 3.7). In addition to these comparisons, more than 50% of the DMRs among HSPCs were in open seas (Table 3.4). Thus, functional epigenetic differences during early human hematopoietic differentiation occur in CpG sparse regions, consistent with other recent studies of differentiation (Irizarry et al., 2009; Ji et al., 2010) and cancer (Hansen et al., 2011; Irizarry et al., 2009).

DMRs for Normal Hematopoiesis are Enriched in Super-enhancers

In order to further investigate a direct mechanistic link between DNA methylation change and regulation of hematopoietic development, we examined the overlap of DMRs that we identified for normal hematopoiesis in DNA regulatory elements, super-enhancers. Super-enhancers are clusters of transcriptional enhancers bound by master transcription factors, and associated with genes that define cell identity and tissue types (Hnisz et al., 2013; Whyte et al., 2013). From a published study that has identified super-

enhancer in 86 different human cell and tissue samples, we selected three categories of tissue types; first, normal cell types related to hematopoietic development such as CD34+ (hematopoietic progenitor cells) and CD14+ (monocytes), second, cell lines related to hematological disorders including jurkat, K562 and MM1S, third, other normal tissues or cell lines including H1, adipose, angular gyrus, and spleen. First, we examined the enrichment of DMRs from normal hematopoiesis including HSC vs GMP and HSC vs MEP comparisons, in super-enhancers of the different tissues or cell types. Remarkably, DMRs for GMP differentiation were significantly enriched in relevant cell types including monocytes and CD34+ cell population (Table 3.5). We identified master transcription factors showing differential methylation as HSC differentiates into GMP, such as *ZNF217*, known to be involved in cell proliferation (Figure 3.8a and Table 3.6, see Appendix3). Among the DMRs of HSC vs GMP comparison, contained within super-enhancers of monocytes, 27.9% was located in monocyte (CD14+ cells) specific super-enhancers (Table 3.6, see Appendix3). For example, a DMR of *TREMI* that encodes a receptor expressed on monocytes was located in a monocyte specific super-enhancer and showed hypomethylation along with upregulation in GMP (Figure 3.8b and Table 3.6, see Appendix3). In addition to the relevant cell types, the DMRs of HSC vs GMP were overlapped with super-enhancers of jurkat and MM1S cells whereas, DMRs distinguishing MEP from HSC are enriched in K562 cells, implying involvement of epigenetic deregulation of the regulatory region in disease pathogenesis.

Human Hematopoiesis Displays Distinct Epigenetic Regulation Compared to Murine Hematopoiesis

In addition to these genomic regional changes, there was an overall global change in the level of DNA methylation in human hematopoiesis (Figure 3.9 and Table 3.4). Global hypomethylation was observed upon MEP differentiation from CMP, but not in GMP differentiation, and most DMRs distinguishing MPP from CMP were less methylated in CMP in human hematopoiesis (Figure 3.9 and Table 3.4). We also found that all DMRs lost methylation when L-MPP differentiates into GMP (Figure 3.9 and Table 3.4). Previous epigenetic study of mouse hematopoiesis (Ji et al., 2010) allowed us to compare human and mouse hematopoietic differentiation for two pairs, MPP vs CMP and CMP vs GMP. We examined overlap of genes of DMR lists of the two comparisons. In both comparisons, most of the genes were different with only 4-5% of total genes in human overlapping with mouse: 7 out of 166 genes of MPP vs CMP, and 30 out of 728 genes of CMP vs GMP (Table 3.7, see Appendix4). Among the 7 and 30 common genes for the two comparisons, 5 and 14 of them showed the opposite direction of methylation changes for the MPP vs CMP and CMP vs GMP pairs, respectively. For example, *VKORC1L1* that encodes a subunit of the vitamin K epoxide reductase complex, was hypermethylated when CMP differentiate into GMP in human, but hypomethylated in the CMP to GMP transition in mouse (Table 3.7, see Appendix4). These results suggest that there is great variability in the specific epigenetic sites regulating mouse and human hematopoiesis.

Discussion

The role of DNA methylation in hematopoietic development has been implicated in several studies that have shown an indispensable role of DNMT1, DNMT3A, and

DNMT3B in hematopoiesis (Broske et al., 2009; Challen et al., 2012; Tadokoro et al., 2007; Trowbridge et al., 2009). In addition, dynamic DNA methylation changes during hematopoietic development in mouse and human have been demonstrated (Bartholdy et al., 2014; Bock et al., 2012; Ji et al., 2010). In order to provide a comprehensive methylome map of human hematopoiesis, particularly myeloid lineage, we analyzed genome-wide DNA methylation of a complete set of HSPCs in myeloid lineage. Our study suggested several significant findings for the epigenetic basis of human hematopoietic development. First, global hypomethylation is a core mechanism of hematopoietic differentiation, as MPP to CMP, CMP to MEP, and L-MPP to GMP differentiations were accompanied by loss of methylation (Figure 3.9). In addition to identifying previously known and novel candidate genes during hematopoietic differentiation, we found that DNA methylation were likely to occur at regulatory elements such as super-enhancer, suggesting a critical role of epigenetics in gene expression of lineage specific genes. Furthermore, we found distinct epigenetic plasticity between human and mouse hematopoiesis. We observed few overlaps of genes with DNA methylation changes between mouse and human hematopoiesis. Besides the distinct study design and experimental platform between the studies, intrinsically distinct mechanisms exist in hematopoietic development in mouse and human. For example, human blood contains 3 to 5-fold more neutrophils than mouse, while mouse blood has 2 fold more lymphocytes, indicating differences in the generation of specific types of hematopoietic progenitor cells (Mestas and Hughes, 2004). Furthermore, mouse hematopoietic system is composed of a different set of HSPCs, and a different set of cell surface markers for HSPCs are used to isolate each population. For example, multiple

subpopulations constitute an MPP compartment, and Flk2 and Slamf1 are used to differentiate those subpopulations (Bock et al., 2012; Chao et al., 2008; Doulatov et al., 2012; Ji et al., 2010).

We could compare our results to previous DNA methylation study of human hematopoiesis, and found few common observations, yet there were many distinct and novel findings in this study. We observed global hypomethylation when MPPs differentiated into CMPs, as Bartholdy et al. has reported. However, we identified global hypomethylation in CMP to MEP transition, while Bartholdy et al. has observed balanced hyper and hypomethylation in this differentiation (Bartholdy et al., 2014). In addition, we noticed that DMR lists from all pair-wise comparisons among HSPCs ($p < 0.01$) of our study significantly differed from 561 loci distinguishing LT-HSC, ST-HSC, CMP, and MEP, identified in Bartholdy et al. 51 out of 3613 (1.4%) DMRs of our lists including DMRs in *KLF1* and *GATA1*, overlapped with the 561 loci from Bartholdy et al. The discordance between our study and Bartholdy et al. may come from two major sources: a different set of HSPCs and methods used in those studies. Our study includes two more progenitor populations, L-MPP and GMP, beside HSC, MPP (called as ST-HSC in Bartholdy et al.), CMP, and MEP. We have used 450K array which interrogate ~48000 CpGs across the genome without a bias toward CpG islands and gene promoters, while HELP_Promoter array, used in Bartholdy et al., examines ~26000 loci, primarily targeting gene promoters.

In summary, we provide a comprehensive methylome map of a complete set of HSPCs in myeloid lineage, demonstrating the role of DNA methylation at regulatory

elements during lineage differentiation and dynamic epigenetic plasticity distinguishing human hematopoiesis from murine hematopoietic development.

Materials and Methods

Human Samples

Fresh human bone marrow mononuclear cells (BMMC) from healthy donors (2×10^8 cells per donor, Catalog#: ABM006) were purchased from ALLCELLS[®] (Emeryville, CA). A CD34⁺ cell-enrichment step was performed with the human progenitor cells enrichment kit with CD61 depletion (Stem Cell Technologies, Canada, Catalog # 19356) on a RobSep machine from the same company. PBMC or BMMC were separated with Ficoll-Paque Plus (Amersham Biosciences, Piscataway, NJ, Catalog number: 17-1440-03), and cryopreserved in 1 x freezing medium (90%FBS + 10%DMSO).

Flow Cytometry Analysis and Cell Sorting

A battery of antibodies (Abs) was used for staining, analysis and sorting of progenitor cells from either healthy BMMCs, as well as lineage analysis human chimerism/engraftment (Table 3.2). Cells were either analyzed or sorted using a FACS Aria II cytometer (BD Biosciences, Franklin Lakes, NJ). Analysis of flow cytometry raw data was done with FlowJo Software (Treestar, Ashland, OR).

Illumina Infinium Human Methylation 450 Bead Array Assay

Genomic DNA from each sample was purified using the MasterPure DNA purification kit (Epicentre) according to the manufacturer's protocol. The genomic DNA (250-500ng) was treated with sodium bisulfate using the Zymo EZ DNA Methylation Kit (ZYMO Research) as recommended by the manufacturer, with the alternative incubation

conditions for the Illumina Infinium Methylation Assay. Converted DNA was eluted in 11ul of elution buffer. DNA methylation level was measured using Illumina Infinium HD Methylation Assay (Illumina) according to the manufacturer's specifications. Methylation array data are deposited at the Gene Expression Omnibus (GEO) with accession number GSE63409.

Illumina Infinium Human Methylation 450 Bead Array Analysis

Raw intensity files were obtained using minfi package (Aryee et al., 2014) to calculate methylation ratios (Beta values). The data was normalized using Illumina preprocessing method implemented in minfi. Several quality control measures were applied to remove arrays with low quality. Control probes were examined on the 450k array to assess several measures including bisulfite conversion, extension, hybridization, specificity and others. One of the MPP samples (BM2712) showed low quality for the measures, so they were removed for further analysis. Next, median methylated and unmethylated signals were calculated for each arrays; no array was identified for signal values lower than 10.5. For multidimensional scaling analysis, probes containing an annotated SNP (dbSNP137) at the single-base extension or CpG sites were removed (17398 probes removed). Minfi 1.8.9 was used.

Bump hunting method previously described was applied to identify DMRs in 450k array (Aryee et al., 2014; Jaffe et al., 2012). Beta value of 0.1 (10% of methylation difference) was used as cutoff when finding DMRs. Statistical significance was assigned by permutations testing and the P-value cutoff used for downstream analysis was <0.01 that corresponded to Benjamini-Hochberg adjusted p-value <0.1 (data not shown) unless different cutoff was designated in result part. Bumphunter 1.2.0 was used.

Bisulfite Pyrosequencing

100ng of genomic DNA from each sample was treated with sodium bisulfate using an EZ DNA methylation Gold Kit (ZYMO research) following manufacturer's protocol. The bisulfate treated DNA was PCR amplified using unbiased nested primers. Quantitative pyrosequencing was performed using a PSQ HS96 (Biotage) to validate DMR regions. The DNA methylation percentage at each CpG site was measured using the Q-CpG methylation software (Biotage). SssI treated human genomic DNA was used as 100% methylated controls and human genomic DNA amplified by Repli-G mini kit (Qiagen) was used as the non-methylated (0%) DNA control. Table 3.8 provides the primer sequence used for the pyrosequencing reactions with the chromosomal coordinates in the University of California at Santa Cruz February 2009 human genome assembly (hg19) for each CpG site investigated.

Affymetrix Microarray Expression Analysis

Total RNA was extracted from each FACS-sorted cell population using RNeasy® Plus Mini (QIAGEN, Valencia, CA, Catalog#: 74134) according to the manufacture's protocol. All RNA samples were quantified with 2100 Bioanalyzer (Agilent Technologies, Santa Clara, CA), subjected to reverse transcription, two consecutive rounds of linear amplification, and production and fragmentation of biotinylated cRNA. 15µg of cRNA from each sample was hybridized to HG U133 Plus 2.0 microarrays. Hybridization and scanning were performed according to the manufacture's instruction (Affymetrix). This step was performed at the PAN center of Stanford University. Data were normalized by GC robust multi-array average method and analyzed on R/Bioconductor. BM2770 GMP, BM 2759 L-MPP, BM2761 CMP, BM2770 CMP were

removed from further analysis due to low quality (GEO GSE63270). University of California at Santa Cruz February 2009 human genome assembly (hg19) for each CpG site investigated.

Affymetrix Microarray Expression Analysis

Figure 3.6. Location of DMRs for normal hematopoiesis relative to CpG island. Left panel shows proportion of DMRs located in CpG island, overlapping region (50% overlap with island), shore, shelf, and open sea. Right panel shows distribution of length-matched random regions relative to CpG island, overlap, shore, shelf, and open sea. **(a)** HSC vs GMP. **(b)** HSC vs MEP.

a**b**

Figure 3.7. Gene expression inversely correlates with DMRs at non-CpG island regions in normal hematopoiesis. DMRs located within 2kb of gene TSSs (black dots) were classified into 4 groups according to the distance relative to CpG island: island, shore, shelf, and open sea. DMRs located further than 2kb of gene TSSs are denoted as black pluses in the middle. Log2 ratios of differential expression were plotted against differential methylation (all values are from group2-group1). Wilcoxon rank-sum test was performed to test the null hypothesis that the expression differences for the hypo- or hypermethylated DMRs within 2kb of gene TSSs (black dots) showed stronger inverse correlation than the expression differences of the random DMRs that are located further than 2kb of TSSs (black pluses). Random DMRs were shown in the middles of DNA methylation axis regardless of their methylation differences. **(a)** For HSC vs GMP, shore showed statistically inverse correlation of DMR with gene expression. **(b)** For HSC vs MEP, shore and open sea showed statistically inverse correlation of DMR with gene expression.

Figure 3.8. Examples of DMRs located in master transcription factor or super-enhancer. (a) *ZNF217*, a master transcription factor in monocyte differentiation. (b) *TREM1*, located in monocyte specific super-enhancer.

Figure 3.9. Global methylation changes during hematopoietic development in human and mouse. The direction of global methylation change is shown for each comparison in red for human and blue for mouse hematopoiesis. The dotted lines represent two comparisons shared between the studies for human and mouse hematopoiesis.

Chapter 4

The cell of origin of leukemia stem cell

This work is an ongoing project of the Feinberg Lab and Johns Hopkins. All publication rights are reserved for these institutions and the presentation of this work here does not preclude future publication elsewhere.

Summary

The question of the cell of origin of LSC has long been remained in the field, yet much of it still needs to be understood. We hypothesized that DNA methylation could be useful to infer the cell identity of LSCs compared to HSPCs, as it has been shown that transformed or reprogrammed cells retained an epigenetic memory of the cell of origin (Kim et al., 2010; Kim et al., 2011; Polak et al., 2015). We were able to provide a clue for the cell of origin of LSCs by comparing the DNA methylation profile of LSCs to normal HSPCs, obtained from previous chapter. Clustering analysis based on DNA methylation status showed LSCs clustered with either L-MPP or GMP. This result was replicated in TCGA data set, a larger cohort, and supported by molecular characteristics of each cluster such as FAB types, genetic mutations, and cytogenetic risk groups. These results suggested L-MPP and GMP would be major sources of LSCs.

Results

LSC Forms Two Clusters with L-MPP-like and GMP-like

In order to relate normal hematopoiesis to LSC, we first identified the DMRs from all possible pairwise comparisons among the 6 HSPC after applying a more rigorous cutoff of $FWER < 0.1$ (Table 4.1). The resulting 216 DMRs were applied in clustering analysis including all 6 normal HSPC populations with LSCs and Blasts

(Figure 4.1). Strikingly, this analysis revealed that AML samples formed 2 distinct clusters, L-MPP-like and GMP-like (Figure 4.1). Importantly, the GMP-like cluster included several CD34⁺CD38⁻ subpopulations, indicating that these clusters could not have been identified by immunophenotype alone. Moreover, clustering analysis using an equal number of length-matched random regions showed that the clustering of AML populations with either L-MPP or GMP was unique to the selected DMRs (Figure 4.2).

TCGA AML Samples Form Two Major Clusters, L-MPP-like and GMP-like

Strikingly, using the same 216 DMRs, the TCGA samples also formed the same two major clusters, L-MPP-like and GMP-like (Figure 4.3). In addition to the two major clusters, we also identified a minor CMP-like cluster that was not observed in our smaller cohort. We calculated scores indicating the similarity of each TCGA sample to each of the six progenitors, and designated a counterpart HSPC population for each TCGA sample based on highest similarity. This approach showed that 76.6% of TCGA samples resembled GMP and 14.6% had a methylation profile most similar to L-MPP (Figure 4.4).

We hypothesized that if the assignment of AML samples to L-MPP-like and GMP-like clusters was related to the cell of origin, then the degree of maturity and morphology might differ between the two groups. Consistent with this, we compared the distribution of the French-American-British (FAB) classification of the TCGA samples and found that the L-MPP-like cases mainly consisted of more immature M0, M1, and M2 types, while the more differentiated M4 and M5 types were enriched in GMP-like AML ($p < 1 \times 10^{-4}$, chi-square test, Figure 4.5). It should be noted that the LSC epigenetic signature is not merely a recapitulation of FAB types, as our signature is prognostic in multivariate analysis while FAB types are not. In addition, it is not possible to know the

cell of origin simply by examining FAB types (Table 4.2). For example, in 38 cases of M1 AML, 29/38 are GMP-like and 9/29 are L-MPP-like (Table 4.2).

Finally, we sought to investigate if the L-MPP-like and GMP-like clusters, and therefore the potential cell of origin, were associated with cytogenetic abnormalities or recurrent mutations of specific genes including *DNMT3A*, *IDH1*, *IDH2*, *TET1*, *TET2*, *FLT3*, and *NPM1*. The GMP-like cluster was enriched for patients in the low and intermediate cytogenetic risk groups, while the L-MPP-like cluster was enriched for patients in the high cytogenetic risk group ($p=1 \times 10^{-4}$, Fisher's exact test; Figure 4.6a). We found that *IDH1* and *IDH2* mutations were enriched in the L-MPP like group ($p < 0.01$ for both, Fisher's exact test), and *FLT3* and *NPM1* mutations were enriched in the GMP-like group ($p < 0.01$ for both, Fisher's exact test). *DNMT3A* and *TET1* mutations were more enriched in the L-MPP group, but this was not statistically significant (Figure 4.6b). Together, these results demonstrate that DNA methylation signatures permit a novel clustering of AML into L-MPP-like and GMP-like groups that may reflect the cell of origin for each case and demonstrate an association with key disease features.

Discussion

As DNA methylation is a potential marker of cell identity, here we compared DNA methylomes of normal HSPC to LSC as a marker for the cell of origin in AML. Using this approach, we observed two subtypes in our cohort: L-MPP-like and GMP-like. These two subtypes were also identified in the TCGA cohort, suggesting that leukemic transformation predominantly occurs at either the L-MPP or GMP stage of hematopoietic development. We found that other features of AML were associated with these two

subtypes including FAB type, several mutations, and cytogenetic abnormalities, suggesting that the cell of origin may drive key clinical features in AML.

We newly identified a small subset of AML cells clustering with CMP and few samples clustering with HSC, MPP, and MEP that could not be identified in smaller datasets including our own data and a previous study (Goardon et al., 2011). The result from TCGA indicates that the cell of origin of AML could be variable among HSPCs. The result for the cell of origin should be considered carefully, as it is hard to provide definite proof of the question due to experimental limitations. Despite this caveat that affects all of human primary cancer biology, we do provide the first epigenetic evidence for cell of origin in human leukemia and believe that our approach using epigenomic profiles suggests an efficient way to study cell of origin in cancer biology using large data sets.

Materials and Methods

Illumina Infinium Human Methylation 450 Bead Array Assay

Genomic DNA from each sample was purified using the MasterPure DNA purification kit (Epicentre) according to the manufacturer's protocol. The genomic DNA (250-500ng) was treated with sodium bisulfate using the Zymo EZ DNA Methylation Kit (ZYMO Research) as recommended by the manufacturer, with the alternative incubation conditions for the Illumina Infinium Methylation Assay. Converted DNA was eluted in 11ul of elution buffer. DNA methylation level was measured using Illumina Infinium HD Methylation Assay (Illumina) according to the manufacturer's specifications.

Methylation array data are deposited at the Gene Expression Omnibus (GEO) with accession number GSE63409.

Illumina Infinium Human Methylation 450 Bead Array Analysis

Raw intensity files were obtained using minfi package (Aryee et al., 2014) to calculate methylation ratios (Beta values). The data was normalized using Illumina preprocessing method implemented in minfi. Several quality control measures were applied to remove arrays with low quality. Control probes were examined on the 450k array to assess several measures including bisulfite conversion, extension, hybridization, specificity and others. One of the MPP samples (BM2712) and two samples of TCGA (Patient ID: 2934 and 2827) showed low quality for the measures, so they were removed for further analysis. Next, median methylated and unmethylated signals were calculated for each arrays; no array was identified for signal values lower than 10.5. For multidimensional scaling analysis, probes containing an annotated SNP (dbSNP137) at the single-base extension or CpG sites were removed (17398 probes removed). Minfi 1.8.9 was used.

Bump hunting method previously described was applied to identify DMRs in 450k array (Aryee et al., 2014; Jaffe et al., 2012). Beta value of 0.1 (10% of methylation difference) was used as cutoff when finding DMRs. Bumhunter 1.2.0 was used.

Statistical Analysis

To assign cell identity of normal HSPCs to TCGA samples, mean methylation value of each 216 DMRs for normal hematopoiesis (methylation profile) was retrieved and standard deviation of the mean value for each signature was calculated. Then scores (probability density values as log value) for each TCGA sample regarding normal HSPCs' profile was calculated using dnorm function with the mean and standard deviation

calculated in previous step. Maximum value of scores among the ones regarding normal HSPC methylation profile was chosen, and then cell identity assigned.

For clustering analysis, hclust function with ward method in R was used to generate all the cluster dendrogram analysis.

Figure 4.1. Epigenetic signatures define subgroups of AML LSC reflecting the cell of origin. A total of 216 DMRs identified from all possible pairwise comparisons among 6 HSPCs were used to cluster all normal HSPC with all AML subpopulations. The primary AML subpopulations form two major clusters: L-MPP-like and GMP-like. LSC subpopulations are indicated in bold.

Figure 4.3. Epigenetic signatures define subgroups of AML samples in TCGA reflecting the cell of origin. Clustering analysis of TCGA AML samples with normal human HSPC using the 216 DMRs shows that the L-MPP-like and GMP-like clusters are observed in this cohort as well.

Cell type	TCGA	%
HSC	1	0.5
MPP	3	1.6
L-MPP	28	14.6
CMP	12	6.3
GMP	147	76.6
MEP	1	0.5
	192	100

Figure 4.4. Cell identity of TCGA AML samples. TCGA samples were classified into one of HSPC populations according to their DNA methylation profile by generating methylation profiles of all the normal HSPC, and then calculating scores of each sample based on the closest population. The normal progenitor cell identity for each TCGA samples is summarized in this table.

Figure 4.5. Distribution of FAB types for L-MPP-like and GMP-like TCGA AML samples. The L-MPP-like and GMP-like TCGA samples were grouped according to their FAB classification. NA: not classified.

a

Cell identity	Favorable	Intermediate/Normal	Poor
GMP-like	33	90	22
L-MPP-like	0	13	15

b

	L-MPP (%)	GMP (%)
DNMT3A	33.3	25.0
IDH1	33.3	6.3
IDH2	29.6	5.6
TET1	3.7	0.7
TET2	7.4	7.6
NPM1	3.7	34.7
FLT3	7.4	32.6

Figure 4.6. Correlation of disease features with cell identity. (a) Number of TCGA samples that belong to each cytogenetic risk group is shown for GMP-like and L-MPP-like AML samples. Information on cytogenetic risk group was retrieved from clinical annotation of TCGA patients. (b) Percentage of AML samples with specific mutations including *DNMT3A*, *IDH1*, *IDH2*, *TET1*, *TET2*, *NPM1*, and *FLT3* are shown for L-MPP-like and GMP-like AML samples. Mutations that showed statistical significance of association with specific cell types are colored in red. Information on mutations was retrieved from TCGA Mutation Annotation Format (MAF) file.

EDUCATION

2009-present **Johns Hopkins University School of Medicine**, Baltimore, MD

PhD Candidate in Cellular and Molecular Medicine Graduate Program.

Thesis advisor: Andrew P. Feinberg, MD.,MPH.

2003-2007 **Pohang University of Science and Technology (POSTECH)**, Pohang,
South Korea

B.S. in Life Science, **Summa Cum Laude**.

Thesis advisor: Yun-je Cho, PhD.

2005 **University of California, Berkeley**, Berkeley, CA

Exchange student in Dept. of Molecular and Cellular Biology.

RESEARCH EXPERIENCE

2009-present **Johns Hopkins University School of Medicine**, Center for Epigenetics
and Department of Medicine

PhD candidate, Thesis advisor: Andrew P. Feinberg, MD.,MPH.

Investigated the role of epigenetics, particularly DNA methylation in progenitor cell biology. Two major model systems were explored; Leukemia stem cells (LSCs) along with normal hematopoietic stem and progenitor cells (HSPCs), and induced pluripotent stem cells (iPSCs).

a. Epigenetic features of LSCs and HSPCs using Illumina Infinium HumanMethylation450 bead chip array.

Collaboration with Ravindra Majeti, MD., PhD. at Stanford University School of Medicine.

-Identified LSC epigenetic signature, DNA methylation differences that correlates with differential gene expression between LSCs and blasts.

-Demonstrated prognostic power of LSC epigenetic signature for AML patients.

-Discovered novel regulators for human hematopoiesis with genome-wide DNA methylation and gene expression analysis.

-Identified subgroups of LSCs that reflect cell of origin with DNA methylation analysis.

b. Epigenetic differences of iPSC clones derived by different non-integrating methods using mRNA, sendai virus and episome with whole genome bisulfite sequencing (WGBS) and chromatin immunoprecipitation sequencing (ChIP-seq) analysis.

Collaboration with George Q. Daley, MD., PhD. at Harvard University School of Medicine.

-Identified no significant DNA methylation differences among the iPSCs derived from different methods

2008-2009 **Yonsei University**, Center for Genome Regulation (Seoul, South Korea).

Research assistant, Supervisor: Youngjoon Kim, PhD.

-Optimized native ChIP and identified specific methylation patterns in obesity and cancer.

2007 **Swiss Institute for Experimental Cancer Research (ISREC)**, Telomerase and Chromosome End Replication Laboratory (Lausanne, Switzerland).

Summer research program student. Research advisor: Joachim Lingner, PhD.

-Identified the function of *Rat1*, an exonuclease involved in DNA transcription termination, replication and telomere senescence in *Saccharomyces. Pombe*.

- 2006-2007 **Pohang University of Science and Technology (POSTECH)** (Pohang, South Korea)
- Undergraduate student, Thesis advisor: Yunje Cho, PhD.
- Performed structural study of *MCM10*, a member of DNA replication complex in eukaryote.
- 2006 **Pohang University of Science and Technology (POSTECH)** (Pohang, South Korea)
- Undergraduate student, Research advisor: Sungho Ryu, PhD.
- Studied the relationship between glycolysis and mTOR pathway.
- 2005 **Pohang University of Science and Technology (POSTECH)** (Pohang, South Korea)
- Undergraduate student, Research advisor: Byung-ha Oh, PhD.
- Conducted preliminary structural study of autophagy complex.

HONORS & AWARDS

- 2014 Mogam Scholarship
- 2009-2014 Samsung Scholarship
- 2007 Academic Scholarship for EPFL (Ecole Polytechnique Federale de Lausanne) Summer Research Program
- 2007 Summa Cum Laude, POSTECH
- 2007 Nuri Scholarship for excellent research project, KRF (Korea Research Foundation)
- 2003-2007 Full Scholarship for talented undergraduate students in science major, KOSEF (Korea Science and Engineering Foundation)

TEACHING EXPERIENCE

- 2009-present **Johns Hopkins University School of Medicine**, Mentor for rotation students.

-Taught how to perform experiments such as bisulfite pyrosequencing, WGBS, comprehensive high-throughput arrays for relative methylation (CHARM), genomic DNA extraction.

-Guided rotation students to make an academic poster and give a talk.
